Soviet men of science are planning an ascent into the stratosphere in July. The ascent will be made in a balloon which is being specially built for the purpose under the supervision of the Leningrad Section of Osoaviakhim (Society for Air and Chemical Defence). Attached to the balloon will be a large, hermetically sealed gondola in which the investigators will be seated. They will wear special clothing and will be equipped with parachutes in case a forced landing is necessary. A meeting of the committee which is arranging the flight has recently been held in Leningrad. It is proposed to make the ascent from the central part of European Russia. The exact point has not yet been decided upon. A trial 12 km. flight into the stratosphere will first be made in order to accustom the investigators to the experimental conditions. The engineer in charge of construction of the balloon, Mr. Chertovsky, and Mr. Vasenko, its designer, are to make the trial flight. In July it is planned to penetrate to a height of 22 km. Among those making the ascent will be Prof. Rynin, a well-known authority on aeronautics, and, health permitting, M. Joffe, an eminent Soviet physicist and member of the Soviet Academy of Sciences.

The Great Siberian Meteorite

A special meteorite commission has been appointed by the Soviet Academy of Sciences to investigate the traces of the large meteorite which fell in the Enisseisk district of Siberia on June 30, 1908. The commission is making preparations to set out on an expedition to the Tungus swamps some time this summer under the leadership of the Soviet meteorologist, Mr. Leonid Kulik. This is the fourth expedition that has been led by Mr. Kulik to search for traces of the Tungus meteorite. The expedition sent out in 1927 discovered in the place where the meteorite fell uprooted trees over a radius of scores of kilometres, their tops towards the centre. Trees blown down by the wind were lying over an area of fifty kilometres from the falling place of the meteor, and the whole locality over a radius of twenty kilometres from the centre was scorched by the high temperature produced. The expedition of 1929 carefully examined the northern section of the central area of the wind-felled wood and made some excavations in the centre. The exploration of the southern part of this wood confirmed the belief that the meteorite had fallen in that spot. The first three expeditions led to the discovery of immense areas of wind-felled trees and traces of burning, but no specimens of the meteorite were found. The aim of the new expedition is to find the exact place of the submerged crater and if possible to obtain specimens of the meteorite itself. In April 1930 Dr. F. J. W. Whipple read a paper on the meteorite and its effects before the Royal Meteorological Society under the title "The Great Siberian Meteor and the Waves, Seismic and Aerial, which it Produced" (*Quar. J. Met. Soc.*, vol. 56, July 1930).

Research and the Linen Industry

In presenting the report at the thirteenth annual general meeting of the Linen Research Association on December 12, 1932, Mr. H. L. McCready, chairman of Council, referred to the importance of research in promoting the welfare of the linen trade and the restoration of prosperity. Due mainly to a reduction of £1,000 in each of the grants from the Empire Marketing Board for flax and fibre production work and from the Department of Scientific and Industrial Research, there was an excess of £2,837 of expenditure over income, £1,444 of this being represented by reserves for rent and depreciation. In spite of drastic economy, however, it was possible to develop during the year what appears to be a much improved and more economical method of treating flax. An entirely new system of handling the material was evolved, existing machinery was improved, new machines designed and constructed, and a superior article of good colour, straight, parallel and clean was produced. Useful work was carried out on various aspects of the bleaching and dyeing of both yarn and cloth. A good deal was discovered about the effect of various reagents on the strength of the fibre. The increased use of coloured effects for borders and checks caused attention to be given to the dyes used and information of the utmost importance regarding various dyes was obtained. The director of research, Dr. W. H. Gibson, underlined the emphasis which Mr. McCready laid on the service aspects of research. There has been a strong tendency for the research work at every stage of the industry to be influenced by questions relating to the raw material on one hand or the requirements of the consumer on the other. The research worker has to take a comprehensive rather than a sectional view of the industry, and research is increasingly demonstrating its ability to give the consumer better service and better value, particularly in relation to the durability of fabrics in washing.

Essential News

For those persons who are interested in the world situation but have not the time or the opportunity to gather the necessary information and facts for themselves, *Essential News*, which is a weekly non-party bulletin, should serve a useful purpose. It is composed of quotations from various papers or periodicals and summaries of significant facts, together with constructive suggestions drawn from English and foreign sources. Thus, in a recent number special attention is devoted to economic reconstruction in Europe. There is a description of Delaisi's Five Year Plan for Europe, which advocates the planning of large schemes of work to reduce unemployment in Europe. The plan envisages the construction of great roads running north and south connecting the Baltic, Poland, the Danubian countries and the Mediterranean. This would open up an immense area in which some sixty million peasants are still living a primitive economic life. Another article in the same issue also bears on the construction of international roads; this is an extract from a pamphlet by Mr. J. E. Meade entitled "Public Works in their International Aspect". According to Mr. Meade, roads are cheaper to build than railways. The nineteenth century provided capital for railways; could not, he asks, the twentieth provide it for special motor roads? A European network of roads, roughly 9,000 miles in extent, financed by a European petrol tax of approximately one penny per gallon, built over a period of five years, would provide work for 188,000 workers in the first year, rising to three quarters of a million in the fifth year. The cost would be about 170 million pounds (gold). Some such roads already exist, in particular between Cologne and Bonn, between Milan and Turin, Como and Brescia, and one is being built between Rome and Naples.

George Edwards's Picture of the Dodo

THE biographical notice of George Edwards, the eighteenth century naturalist, which appeared in the January issue of *Science Progress*, may be amplified by some points of interest in regard to Edwards's picture of the dodo (*Didus ineptus*). Edwards, himself, tells us in the "Gleanings of Natural History", Part 2, 1760, that the coloured figure of the bird (Plate 294), was copied in 1757, as reduced, from a picture in oil-colours, of its natural size, this about thirty inches high. Further, that the original was drawn in Holland from the living bird from St. Maurice's Island (Mauritius) in the East Indies; that it was the property of Sir Hans Sloane, at the time of his death, becoming afterwards Edwards's property. The owner deposited (1759) the picture in the British Museum "as a great curiosity", and with Sloane's record. The original canvas, it may be mentioned, portrayed various other birds; also a few lizards and a toad. Edwards, however, simply selected the dodo for his plate, adding a guinea-pig for the sake of relative magnitude. It appears that the picture was copied in brighter colours (it was blackened through age) about 1877 by Mrs. L. Gunther, mother of Dr. Albert Günther, keeper of the Zoological Department of the British Museum. From this copy, which is at Oxford, a postcard in colour was ultimately made, and is obtainable at the Old Ashmolean, Oxford. The large picture which hangs in the Bird Gallery of the Natural History Museum, South Kensington, is the original canvas, which has been cleaned; the postcards in colour available at the Museum are reproductions of this picture.

Physical Bibliographies

THE recent issue of the index numbers of the physics and the electrical engineering volumes of *Science Abstracts* completes these volumes for the year 1932. The physics volume deals with 5,364 abstracts in 1,316 pages and the electrical engineering one with 2,926 in 756 pages. While the latter is slightly larger than the 1931 volume and author and subject indexes are on the same lines as in previous years, the former is about twenty per cent larger and its subject index has been greatly improved and its length increased about twenty-eight per cent to 197 pages. Physics papers are divided into eight main classes, each class into sections, with key-headings, and each section into sub-groups with sub-headings. For example, a main class—general physics—has twenty-one key-headings, one of which is elasticity and plasticity. This has ten sub-headings, two of which are photoelasticity and vibrations, with cross references to acoustics, piezoelectricity, seismology and thermodynamics. The key-headings are arranged in alphabetical order throughout the index. These improvements will be welcomed by users of the volume. The *Revue Bibliographique* of the *Journal de Physique* for 1932 is not yet completed but the volume for 1931 devoted approximately 130 pages to the subject index, 160 to author index and 850 to abstracts. In the subject index the whole of the sections under a class appear together and are divided into sub-sections or groups.

Veterinary Publications

WITH the January number (vol. 3, No. 1) the *Veterinary Bulletin* enters upon the third annual volume. A regular monthly issue, begun with vol. 2, will be continued, and by some adjustment of the lay-out of the pages more space will be available for a larger number of abstracts. In this first number, a list is given of the publications from which abstracts will be selected. The *Veterinary Bulletin* is published by the Imperial Bureau of Animal Health, Veterinary Laboratory, Ministry of Agriculture and Fisheries, Weybridge, Surrey, the annual subscription being £2. The Imperial Bureau of Animal Health also proposes to issue, should adequate support be forthcoming, under the title *Index Veterinarius*, a complete index to publications relating to veterinary research, administration, etc. An annual volume in crown quarto size would run to about 1,600 pages and a number, consisting of about 400 pages, would be issued each quarter. The *Index* would be prepared on a Gestetner duplicator: the sheets printed on one side only, clear to read, and adequately glued, stitched, and bound. About 10,000 references would be indexed each year, with cross-indexing. The price would be £4 the annual volume, including postage.

Horticultural Education Association Year Book

It is with great pleasure that we notice the appearance of a Year Book of the Horticultural Education Association for 1932 (South-Eastern Agricultural College, Wye. 3*s*. 6*d*. post free). This volume, which we hope is the first of a long series, contains many items of importance to members of the Association, but also has several articles of general horticultural importance. Horticultural activities in various counties are described by the respective county agents or supervisors. Other articles refer to spray spreaders, vegetable breeding, glasshouse research, vegetable diseases, insecticides and fruit storage problems. The Association and particularly the editor, Mr. R. T. Pearl, are to be congratulated upon the production of a very useful volume at a reasonable price.

Marmite

We have received from the Marmite Food Extract Co., Ltd., London, E.C.3, a booklet describing the medicinal and dietetic value of 'Marmite'. This is an extract of yeast, rich in vitamins B_1 and B_2. Vitamin B helps maintain the appetite and proper function of the digestive tract, and also aids growth, reproduction, and lactation. The reserves in the body are very small, so that a regular daily intake is required. Recent work has shown that 'Marmite' is of value in the treatment of the pernicious anæmia of pregnancy, in the anæmia of sprue and cœliac disease and possibly also in true Addisonian pernicious anæmia: all these anæmias belong to the megalocytic group. Strauss and Castle believe that normal hæmatopoiesis depends upon the interaction of two factors, an intrinsic one present in normal gastric juice, and an extrinsic one occurring in certain foodstuffs, which is abundant in 'Marmite' and may be identical with vitamin B_2. Up to 4 ounces of 'Marmite' may be taken daily by an adult.

Dorothy Temple Cross Research Fellowships in Tuberculosis

The Dorothy Temple Cross research fellowships in tuberculosis for the academic year 1933–1934 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1. The object of these fellowships is to give special opportunities for study and research to persons "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms". Candidates must be British subjects and must possess suitable medical, veterinary or scientific qualifications. The fellowships will preferably be awarded for projected studies or inquiries outside Great Britain. They will be awarded for one year as a rule, and are of the annual value of not less than £350. It may also be possible to award a senior fellowship of considerably greater value for an intensive study of some particular problem of tuberculosis at a chosen centre in another country. Further particulars are obtainable from the Secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1.

Announcements

The Daniel-Pidgeon fund for 1933 of the Geological Society of London has been awarded to Mr. J. D. Solomon, who proposes to undertake the correlation of the Pleistocene deposits of south-eastern England with those of neighbouring parts of the Continent.

Senatore Prince Ginori Conti will read a paper on "The Natural Springs of Tuscany and their Industrial Application" before the Royal Society of Arts, Adelphi, London, on May 3, at 8 p.m. The historical development of the venture and its condition at the present day will be described, and illustrated by a film. The natural steam power developments, with special reference to boracic acid production, at Larderello, Tuscany, were described in an article in Nature of January 14, 1928.

The annual meeting of the members of the Royal Institution for the election of officers and to receive the annual report of the Visitors for the year 1932, will be held on May 1. At the conclusion of the annual meeting a portrait of Sir William Bragg, painted by Mr. William Nicholson, will be presented to the Royal Institution.

The Ministry of Health has issued revised port sanitary regulations (Statutory Rules and Orders, 1933, No. 38) which will come into operation on May 1, together with an explanatory circular (1296). These regulations will replace several regulations of 1907, 1920, and 1929. The aim is to consolidate most of the regulations relating to the control of shipping in ports, and to bring quarantine procedure into line with modern methods of international interchange of information relating to epidemic diseases.

Applications are invited for the following appointments, on or before the dates mentioned:—An assistant borough electrical engineer for the Fulham Borough Council—The Town Clerk, Town Hall, Fulham, S.W.6 (May 8). A professor of mathematics and natural philosophy at the McCrea Magee College, Londonderry—The Secretary of the Faculty (May 10). A headmaster of the Ashton-under-Lyne Junior Technical School—G. W. Handforth, Education Office, 8, Warrington Street, Ashton-under-Lyne (May 13). An independent lecturer in mathematical physics at the Queen's University of Belfast—The Secretary (June 12). A woman teacher of science, agricultural science, gardening, geography, and hygiene at the Shortwood Training College for Women Elementary Teachers, Constant Spring, P.O., Jamaica—The Secretary, Cross Roads P.O., Jamaica. A mechanical draughtsman for the Sudan Railways—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1. Mechanical engineers in the Royal Army Ordnance Corps—The Under-Secretary of State (A.G.9), The War Office, S.W.1.

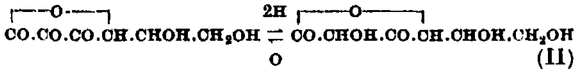
Erratum. In Nature of April 22, p. 565, col. 2, lines 15 and 16, for phrase "one asymmetric carbon atom" read "no asymmetric carbon atom".

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Constitution of Ascorbic Acid

WE have now confirmed the accuracy of the structure (I) $\mathrm{COOH.CO.CO.CHOH.CHOH.CH_2OH}$ which we had previously assigned to the first (reversible) oxidation product of ascorbic acid on the ground that it yields oxalic acid and trihydroxybutyric acid (*l*-threonic acid) on further oxidation[1]. The above formulation represents an open chain acid, but it is now evident that at the moment of formation the substance behaves as a lactone of (I) and not as the free acid. We have already advanced a constitutional formula for ascorbic acid (represented by (II) and its tautomerides) which shows the relationship between (I) and (II) to be as follows :[2]



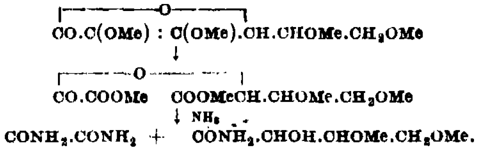
$$\mathrm{CO.CO.CO.CH.CHOH.CH_2OH} \underset{\mathrm{O}}{\overset{\mathrm{2H}}{\rightleftharpoons}} \mathrm{CO.CHOH.CO.CH.CHOH.CH_2OH} \qquad \text{(II)}$$

Strong evidence in favour of these views has been obtained from a study of the properties of the methylated derivatives of ascorbic acid. We find that dimethyl ascorbic acid (III), obtained by the action of diazomethane on ascorbic acid, is a neutral substance which reacts with one equivalent of warm $N/10$ alkali without elimination of methyl alcohol. The formation of the sodium salt appears to involve the opening up of the lactone ring in (III). Both methoxy groups are therefore enolic in character (contrast Karrer[3] and Micheel and Kraft[4]). Profound decomposition occurs when the dimethyl derivative is warmed with strong alkali. In this respect the tetramethyl derivative (see below) is much less stable and on continued heating with $N/10$ alkali it breaks down with elimination of at least three molecules of methyl alcohol.

$$\mathrm{CO.C(OMe):C(OMe).CH.CHOH.CH_2OH} \qquad \text{(III)}$$

The crystalline substance, m.p. 123°, obtained by Micheel and Kraft[5] by the action of methyl alcoholic ammonia on dimethyl ascorbic acid is apparently formed in an analogous manner by the addition of ammonia to the lactone group of (III). The two methoxyl groups of dimethyl ascorbic acid are retained in the product, which we find behaves as an amide. It contains one molecule of combined methyl alcohol and has an empirical formula $C_9H_{19}O_7N$ (not $C_8H_{15}O_6N$).

The nature of the ring system (1 : 4) present in dimethyl ascorbic acid has been determined by the degradative oxidation of tetramethyl ascorbic acid, obtained by the action of methyl iodide and silver oxide on the dimethyl derivative. On treatment with ozone the tetramethyl derivative gives rise to a neutral substance (V) which reacts immediately with ammonia giving quantitatively oxamide and 2-hydroxy 3 : 4-dimethoxybutyramide. Detailed examination of the hydroxy dimethoxybutyric acid has revealed that it consists of two isomerides, the main portion (80 per cent) being 3 : 4-dimethyl-threonic acid, which we have characterised by its conversion into 2 : 3 : 4-trimethyl *l*-threonic acid (amide, m.p. 77°, $[\alpha]_D + 66°$ in water). The remainder was found to be 3 : 4-dimethyl *l*-erythronic acid (amide, m.p. 113°, $[\alpha]_D - 34°$ in water). The amides of both hydroxy acids gave sodium isocyanate on treatment with sodium hypochlorite (Weerman's reaction) and are therefore α-hydroxy derivatives. The isolation of the two epimeric acids suggests that at some stage during the series of reactions enolisation has occurred at C_4. The observation is of special interest in that any possibility of such a change taking place in the plant or animal or during the process of isolating ascorbic acid has great significance from the biological point of view.



$$\mathrm{CO.C(OMe):C(OMe).CH.CHOMe.CH_2OMe} \qquad \text{(IV)}$$
$$\downarrow$$
$$\mathrm{CO.COOMe\quad COOMeCH.CHOMe.CH_2OMe} \qquad \text{(V)}$$
$$\downarrow \mathrm{NH_3}$$
$$\mathrm{CONH_2.CONH_2} + \mathrm{CONH_2.CHOH.CHOMe.CH_2OMe.}$$

The present observations are incompatible with the furane carboxylic acid structure for ascorbic acid advocated by Micheel[4] (which we had previously rejected for crystallographic reasons) and with the formulæ recently suggested by Karrer[6]. The oxidation results demand for tetramethyl ascorbic acid either (IV) or the structure

$$\mathrm{COOMe.C:C(OMe).CH.CHOMe.CH_2OMe,}$$

but apart from its inherent improbability on account of the propylene oxide ring, the latter formula is unable to explain the non-acidic character of the newly-formed first oxidation product of ascorbic acid or the behaviour of the methylated derivatives towards alkali and towards ammonia. On the other hand, all the observations offer strong support to (IV) for tetramethyl ascorbic acid and to (II) and its various tautomeric modifications for free ascorbic acid.

We wish to thank Prof. A. Szent-Györgyi for his kindness in placing at our disposal the ascorbic acid used in this work.

Vitamin B_4 and Adenine

IN a recent preliminary communication, R. Tschesche[1] has directed attention to the similarity between adenine hydrochloride and the crystals isolated by Barnes, O'Brien and Reader[2]. These crystals were specifically stated by them to have vitamin B_4 activity (10γ per diem per rat), but no claim was made that they were actually vitamin B_4. Tschesche does not state whether the specimen of crystals obtained by him was biologically active.

The general resemblance in many respects between the *isolated* crystals and adenine hydrochloride has been familiar knowledge in this laboratory for a considerable time. Before leaving the work in September, V. Reader tested a specimen of adenine hydrochloride (B.D.H.) for vitamin B_4 activity with negative results. In further work it has been found that some crystalline preparations of vitamin B_1[3] in which no adenine is detectable, are still contaminated with highly active vitamin B_4.

Hence, from two independent lines of evidence, vitamin B_4 and adenine cannot be identical. The published analysis of the crystals, though showing general agreement with the formula of adenine hydrochloride, left room for difference. Further unpublished investigations by R. D. Heard and J. R. O'Brien have shown that the crystals with vitamin B_4 activity consist, in fact, largely of adenine[4]. Therefore it now remains to separate and determine the nature of the active residue. The conclusion that vitamin B_4 itself must be active in doses of less than 1γ per diem seems to be irresistible.

It may be added that, so far, irradiated adenine has not exhibited vitamin B_4 activity in our hands.

Absorption Spectrum of the Unsaponifiable Matter from Wheat-Germ Oil

In a recent letter to NATURE, Bowden and Moore[1] record data on the absorption spectrum of the vitamin E fraction of wheat-germ oil. So early as 1928, wheat-germ oil and extracts were studied here. The oil showed a maximum at 272 mμ ($E_{1\,\text{cm.}}^{1\,\text{per cent}}$ 1·9) and the unsaponifiable matter (kindly supplied by Prof. J. C. Drummond) gave evidence of maxima at 280 mμ and 256 mμ, together with weak selective absorption in the visible. On recrystallising, a white solid showing the ergosterol bands and very distinct maxima at 242 mμ and 253 mμ was obtained, whilst the more soluble coloured fraction still showed marked inflexions near 280 mμ and 256 mμ.

About the same time, a vitamin E concentrate from wheat-germ oil, made available by the kindness of Prof. H. M. Evans of California, was studied. The material was an orange solid (mainly sterol), the visible absorption of which suggested a carotenoid. The recrystallised sterol showed the four principal ergosterol bands with additional well-defined maxima at 242 mμ and 253 mμ, whilst the non-crystalline fraction exhibited an inflexion near 250 mμ.

Again last year, we examined an extract from wheat-germ oil kindly supplied by the Glaxo Research Laboratories. The alcoholic solutions showed the following bands :

λ max.	480	448	420	398	280 mμ (inflexion)
$E_{1\,\text{cm.}}^{1\,\text{per cent}}$	4·3	5·3	6	7	80

The material was worked up into a number of fractions without any very striking separation being achieved. The purified sterol contained small but appreciable quantities of ergosterol and an unidentified sterol showing maxima at 242·5 mμ and 252·5 mμ. An inflexion at 255 mμ appeared in some of the fractions from which sterols had been removed.

Early this year, another specimen of wheat-germ unsaponifiable matter was made available by the courtesy of British Drug Houses, Ltd. The maxima at 480, 448, 422 and 398 mμ again appeared in the crude material and in the residues obtained after recrystallisation. The sterol fraction contained ergosterol and the unidentified sterol in comparable amounts (less than 1 per cent of the gross non-saponifiable matter). The non-crystalline fractions exhibited several weak inflexions, notably at 300-310 mμ, 280-290 mμ and *c.* 250 mμ.

The observations of Bowden and Moore are thus confirmed. Further attempts at fractionation will involve high vacuum distillation of reasonably large quantities of material. Our data have not hitherto been published because no definite connexion between vitamin E and selective absorption has yet emerged.

Fundamental State of Nuclear α-Particles

IT is known that γ-rays accompanying α-disintegration are due to the fact that an α-particle can escape from the nucleus with energy less than corresponds to the fundamental level, leaving the resultant nucleus in an excited state[1]. The relative intensities of these 'fine-structure' groups are given by the transparency of the potential barrier for corresponding energies $E(\alpha_n)$:

$$J(\alpha_n) = \exp\left[-\frac{4\pi e^2(Z-2)}{h\sqrt{[2mE(\alpha_n)]}} + \frac{8e\sqrt{m}}{h}\sqrt{Z-2}\,\sqrt{r_{\text{eff}}}\right]$$

$$\sqrt{r_{\text{eff}}} = \sqrt{r_0}\,\Big[1-0{\cdot}002j(j+1)\Big] \quad . \quad . \quad . \quad (1)$$

where j is the azimuthal quantum number of the escaping α-particle. These intensities must rapidly decrease with energy and will be still further reduced in cases when j is not zero in the excited states ; it can be calculated from (1) that this reduction will be respectively 1·3, 4, 16 and 105 times for $j = 1, 2, 3, 4$. Thus we come to the conclusion that, in cases where, for normal decay, the α-particle has $j = 0$, the slow groups of 'fine-structure' will be very weak.

I have shown[2], however, from the examination of irregularities in the change of nuclear radii in the different radioactive families, that for certain elements the normal group of α-particles has j differing from zero ; this seems to be the case for radium-actinium, actinium emanation and also, probably, for actinium C, radium C and thorium C. This means that the nuclei of the original and resultant element possess different spins, which is not so surprising if we remember that, for example, stable nuclei such as Bi^{209} and Tl^{205}, differing only by an α-particle, have spins differing by four units (9/2 and 1/2). For such cases the relative intensity of a normal group will be considerably reduced in favour of slower groups, for some of which the spin-difference between the original nucleus and the excited state of the resultant nucleus may vanish. For such α-transformations the 'fine-structure' will be much easier to detect, as the intensities of slower groups can be even larger than for the normal one.

If we turn now to the experimental evidence[3], we find that it is in radium-actinium, actinium emanation, and the three C-products mentioned above that relatively strong slow groups are present, while for other elements the intensities of these groups are practically on the limit of observation.

From the relative intensities of different 'fine-structure' groups of a given nucleus, it is possible also to determine the corresponding j's. For thorium C, for example, the calculated (for $j = 0$) and observed intensities of different α-groups are shown in the accompanying table :

Name of the group ..	α_1	α_0	α_2	α_4	α_3
Calculated intensity (for $j = 0$)	1·0	0·7	0·03	0·005	0·004
Observed intensity ..	0·3	1·0	0·03	0·002	0·02
Relative decrease ..	17	3·5	5·0	13	1

It may be concluded that for α_1 and α_4 we have $j = 3$, for α_0 and α_2, $j = 2$ and for α_3, $j = 0$ or 1. If we assume the spin-difference between the normal state of the thorium C and thorium C″ nuclei to be 3, we arrive at the following system of excited levels of thorium C″ : $\alpha_1(S)$; $\alpha_0(p)$; $\alpha_2(p)$; $\alpha_4(S)$; $\alpha_3(d$ or $f)$.

It is not possible at the moment to compare the energy levels for all nuclei for which 'fine-structure' is found, as the experimental evidence is not yet complete. The striking similarity between the levels of the nuclei of thorium C″ and actinium X is noteworthy : these two level systems differ from one another only by 40 per cent, which is evidently connected with the change of radius by 20 per cent ($6{\cdot}6 \times 10^{-13}$ and $7{\cdot}9 \times 10^{-13}$).

If we compare, however, the levels excited by α-decay with the level system of the radium C′ nucleus[4] excited by β-decay, we find at once that the energy differences are in the last case about four times larger, which supports the hypothesis that γ-radiation by β-decay is due to proton transitions[5].

Periodicity in the Solarisation of Calcite

REPEATED solarisation due to a prolonged exposure to the light of a quartz mercury lamp was observed by the photoluminescence exhibited by calcite from Nabeto. A definite quantity (0·045 gm.) of the finely granulated specimen was put at suitable intervals of time into the depressions of the sample holder[1] placed 15 cm. underneath the lighted lamp (100 volts, 3·1 amp.) which was employed as a constant source of exciting light. Thus a set of samples was subjected to excitation. A panchromatic plate was then applied, immediately after cessation of excitation, on the sample holder, thus charged with a set of the samples excited for discrete durations of time, the distance between the surface of samples and the photographic plate being 3 mm. After being left two hours, the plate was developed, and the photographic densities of the images generated on the plate by the action of phosphorescent light of the excited samples were determined by means of a microphotometer. The results are shown graphically in Fig. 1, which gives the growth curve of photoluminescence, indicating its periodic reversal under the exciting rays. The ordinates represent the density corresponding to the intensity of phosphorescence and the abscissæ the duration of excitation.

As will be seen, the first maximum of the intensity of luminescence appears at about two hours irradiation. With a still longer irradiation, the luminescence gradually loses in intensity owing to the solarisation of the sample. If the excitation is continued further, a minimum of the intensity of luminescence is reached at about twenty-five hours exposure, and a gradual increase of intensity is then observed again up to the second maximum attained at about thirty-three hours irradiation, after which another reversal begins again. Of course, the intensity of photoluminescence corresponding to the second maximum is very weak as compared with that corresponding to the first maximum. The result is quite reproducible with new samples.

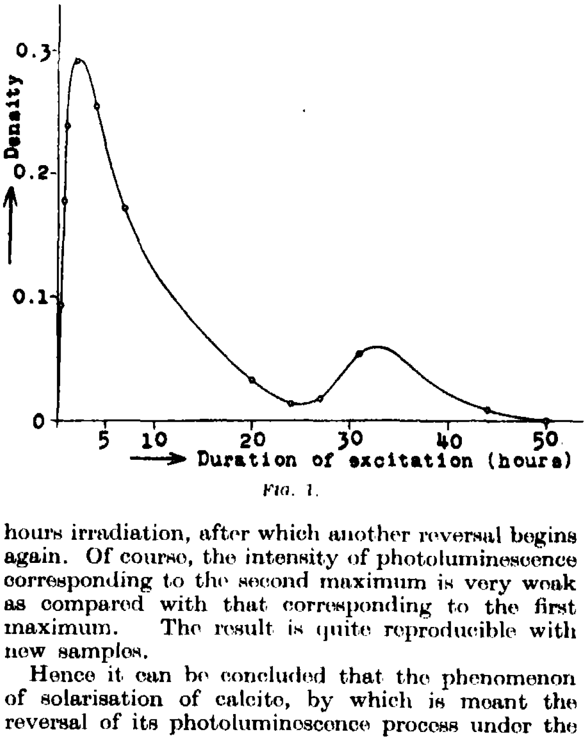

FIG. 1.

Hence it can be concluded that the phenomenon of solarisation of calcite, by which is meant the reversal of its photoluminescence process under the continual action of the light of quartz mercury lamp, is apparently analogous in character to the well-known photographic reversal.

Origin of Cosmic Radiation

EXPERIMENTS seem to show that the cosmic rays are very fast particles, coming from world space ; but at present there is no acceptable theory of the phenomena giving rise to them. Neither Millikan's nor Jeans's hypotheses of nuclear integration or annihilation processes, nor Regener's[1] or Swann's[2] theories, seem to be in accordance with the latest experimental results.

In world space we have a mixture of single atoms and larger particles (cosmic dust, meteors, etc.). Between the single atoms and the larger particles there can be interactions of two different kinds:

A. The single atom collides with the large particle. Then there will be an exchange of energy between the single atom and one of the atoms of the large particle. Processes of this kind will give the single atom a kinetic energy of about the same magnitude as the thermal equipartial energy of the large particle.

B. The single atom, however, can also react with the whole large particle, considered as a giant molecule. This will happen when the atom does not actually collide with, but only passes in the neighbourhood of, the large particle. The energy exchange is then due to the electrical forces. According to the gas kinetic laws, the most probable process is, that the particle with the lower kinetic energy will gain energy. Even if the large particle has a mass of only 10^{10} gram, and a velocity of some km./sec., its kinetic energy is very much higher than that of the single atom. Therefore the kinetic energy of the atom increases at practically every encounter with large particles; and it seems probable that in a sufficient long time the atom can gain even as large energies as the 10^9 or 10^{10} ev., observed in the cosmic rays.

If we suppose, as mean values, that at every encounter with large particles, there is a probability δ (δ is a small quantity) for an A-interaction (at which a fast particle loses energy) and a probability $1-\delta$ for a B-interaction, at which the atom gains an energy ϵ; then after p encounters of every atom, there is left $n(1-\delta)^p$ atoms of n initial atoms, and each of these has gained the energy $p\epsilon$ (as a mean). Consequently, if we plot the numbers of atoms against their energy, we obtain an exponential curve. This is in agreement with the experimental results of Kunze[3].

It seems possible, therefore, to explain the origin of the cosmic rays, introducing no new hypotheses, and only applying the kinetic gas theory to the conditions of world space.

Cathode Ray Photography of Random Electrical Transients

The recent improvements in the design of cathode ray oscillographs have naturally led to an exploration of their use for the external photographic recording of recurrent electrical events and also those of a transient nature which occur at random intervals. In the case of recurrent phenomena, such photography of the cathode ray trace is easy, but for random transients a satisfactory method must ensure that no event is missed and that fruitless exposures are few.

In some experiments carried out last summer, in collaboration with Prof. E. V. Appleton at King's College, we were concerned with the delineation of the rapid changes occurring in the earth's electric field due to both near and distant lightning flashes. These changes caused the fluorescent spot to move horizontally and were recorded on film carried by a revolving drum. By this method a resolution of pulses separated by time intervals of 20 microseconds was obtained, but it was unsatisfactory since the transient had to be anticipated and only a brief exposure was possible owing to the fogging caused by the background illumination of the tube. Methods employing a single time stroke and an electron beam trap were devised to minimise the relative intensity of this compared with the trace, but even so, distinct limitations are imposed.

These difficulties have been overcome by using the special cathode ray oscillograph supplied by Messrs. A. C. Cossor, Ltd., which gives a long after-glow of the red fluorescent trace, together with a form of circuit which gives a faithful oscillographic trace of an event, the occurrence of which is beyond the control of the operator.

The same method may be used to record the changes due to sustained or periodic phenomena occurring during a single sweep of the time base, which therefore obviates the necessity for a synchronisation of the repeated time base to obtain the steady picture necessary for a 'snap' exposure. The transient wave form remains on the screen long enough to enable the camera shutter to be tripped by a thyratron arrangement actuated by a small fraction of the initial voltage. This produces no apparent distortion of the wave form. The correct brief exposure is thus made a short time after the event has finished and a second relay can be used to move the film on to the next position. A valve phase change device ensures that the shutter shall be tripped by both positive and negative initial pulses. The response of the shutter relay system occurring after the electrical event, can be made before any substantial decay of the red after-glow and therefore the exposure is made during high luminescence of the trace compared with the general background. To obtain high photographic sensitivity a camera lens having an aperture of $f/0 \cdot 99$ is used and advantage taken of the special properties of hypersensitive panchromatic film. Records have, however, been obtained on panchromatic film (H. and D. 400) using an ordinary photographic lens of aperture $f/6 \cdot 3$.

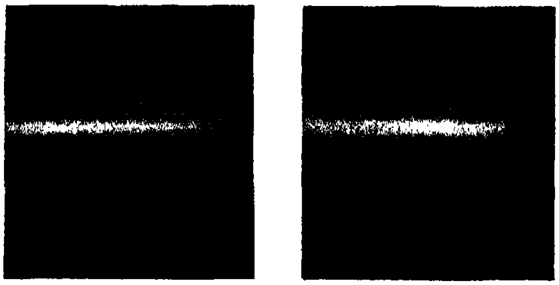

Fig. 1.

Fig. 1 shows two records, twice the size of the originals, of a condenser discharge through two different damping resistances, the exposure in each case being 1/25 sec. Records can be made on either a recurrent time base or 'tripped' single time stroke. In the case of the latter there is, however, the disadvantage that, with the present tube working at a gun voltage of 1500 volts, a stationary electron beam is accompanied by rapid disintegration of the luminescent material at the point of incidence of the beam.

These experiments have been carried out as part of the programme of the Radio Research Board of the Department of Scientific and Industrial Research.

Form and Vibrational Frequencies of the NO_2 Molecule

BAILEY and Cassie[1] have recently presented data on the absorption of $NO_2 - N_2O_4$ gas mixtures in the region from 2·5μ to 16μ, from which they conclude that the NO_2 molecule is linear and symmetrical. As their conclusions and in some respects their data are in disagreement with results obtained recently in this Laboratory, and earlier results[2], we wish to present briefly the facts that lead us to conclude that the atoms in the NO_2 molecule are disposed as an obtuse angle triangle. Detailed reports will be published elsewhere.

The most cogent argument against a linear model is the complexity of the fine structure of the discrete absorption bands in the visible and ultra-violet. The isolated band of NO_2 at 2491 A. clearly shows well-developed branches corresponding to rotations about two different axes of inertia, possible only if the molecule is non-linear in both the normal and excited states. We have examined the structure of the band under high resolution and find additional complexities associated with mutations about the third axis of inertia of magnitude indicating that the molecule is only slightly, but definitely, bent (apex half-angle > 55°) in the normal state. Weaker bands of practically identical structure occur at 751·1 and 1321·1 cm.$^{-1}$ on the long wave-length side of the 2491 A. band. Quantitative measurements of the temperature coefficient of absorption make certain that these frequency differences belong to the normal state, and are presumably the fundamentals ν_2 and ν_1.

In the infra-red we have made measurements with a prism spectrometer from 1μ to 4μ using deep layers of gas under controlled conditions and find a number of bands which we can definitely ascribe to NO_2 or N_2O_4. Those found in NO_2 and the bands found earlier above 4μ can be accounted for as combinations and overtones of fundamentals 751, 1321, and 1621 cm.$^{-1}$. The last fundamental corresponds to the strongest band found at 6·17μ by Warburg and Leithauser and checked by Bailey and Cassie. Frequencies equal to the sum of observed frequencies are found, again excluding the possibility of the linear structure. However, it should be stated that we can also account for all our infra-red bands by using the two frequencies suggested by Cassie and Bailey and assuming an inactive frequency of 1010 cm.$^{-1}$. The infra-red data available do not permit a unique answer as to the structure.

Although lacking details of their experiments, we think it possible to reconcile Cassie and Bailey's data with our model, as follows. The band found by them at 13·4μ is in good agreement with our ν_2 = 751 cm.$^{-1}$, the deformation frequency; that at 6·17μ is the ν_3 fundamental. The fundamental band corresponding to our ν_1 = 1321 cm.$^{-1}$, which should occur at 7·58μ, is missing. Inasmuch as the molecule is only slightly bent, we would expect this band to be the weakest fundamental; and it appears that the amount of gas in the absorbing layer was sufficient to bring out only the strongest bands, since they failed to report the strong 3·43μ band.

All the other bands, and possibly these also, may be ascribed to the N_2O_4 molecule, if the term molecule is not too definite to apply to what may be viewed as a more or less short-lived partnership of two NO_2 groups. In our infra-red work it is found that all the frequencies of NO_2 appear again in N_2O_4, indicating that the association bond is not strong enough to change appreciably the binding within the NO_2 groups. In addition, N_2O_4 has bands due to the extra degrees of vibrational freedom.

On our interpretation, calculation of the moment of inertia of NO_2 from the doublet separation of the 15·6μ band would have no significance; and such a calculation from the 6·17μ band must be regarded with caution, as a *Q* branch should be present. The intensity of the latter would however be small for a slightly bent molecule[3] and might well be missed except by spectrometers of the highest resolution.

Further measurements in the infra-red are necessary to settle the difficulties mentioned above. However, it seems that the moments of inertia of NO_2 will be obtained most accurately from an analysis of the electronic band spectra.

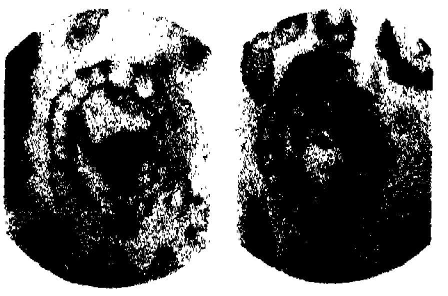
Sporangia containing Spermatozoids in Ferns

ALTHOUGH ferns have in a few instances shown some irregularities in the development of the haploid and diploid generation, such as appertain to apogamy and apospory, there has so far been little concrete evidence to homologise the sexual organs (or their content) with sporangia (or their spores) in ferns. The fact that spermatozoids have now been found in normal sporangia of *Scolopendrium vulgare* may

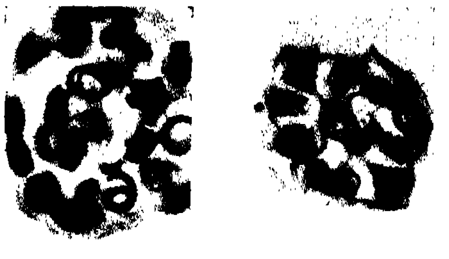


(*a*) (*b*)

FIG. 1. Sporangia with (*a*) spermatozoids, (*b*) spores. × 1350.

thus be of some interest from the phylogenetic point of view and may throw more light on the alternation of generations, which in ferns is of such a stable and characteristic type.

Only a small number of sporangia with spermatozoids have been found among the usual sporangia with spores. Both occur in the same sorus and are equally well developed as to stalk, wall, sequence of divisions, etc. The only difference is that about sixty (in one case possibly only thirty-two) spermatozoids develop instead of the sixty-four spores. In one instance, spermatozoids were almost certainly formed when the cells were still joined in tetrads.



(*a*) (*b*)

FIG. 2. Photomicrographs of spermatozoids in (*a*) sporangium, (*b*) antheridium. × 4200.

These exceptional sporangia have now been observed in fixed material of four normal, fully fertile hybrids between the so-called 'peculiar' and the normal type of *Scolopendrium vulgare*[1]. It is probable that the phenomenon has something to do with the curious life-cycle of the 'peculiar' type.

Lunar Periodicity in Reproduction

IN view of the recent correspondence in NATURE[1] bearing on the question of reproductive periodicity in organisms, I should like to direct attention to some observations made by Miss S. M. Marshall and myself in Australia in 1928-29, which appear to indicate a type of such periodicity not previously recorded. In shallow pools on the Low Isles coral reef, one of the common corals is the branched species *Pocillopora bulbosa*. On some occasions, collections of branches of this coral will give off large numbers of planulæ; at other times, large collections of branches will give off no planulæ at all. During the period August 1928 to July 1929, about eighty collections of branches were made, representing hundreds of colonies. When the results of these collections were plotted, it was found that the production of planulæ was discontinuous, periods of production alternating with periods of no production. In the months December to April the productive periods occurred at about the time of *new moon*; in July and August at about the time of full moon; and in May and June a transition period was demonstrable from new moon to full.

I do not wish to emphasise this result too much, since the number of data is smaller than is desirable; but I am doubtful if it is possible to escape the conclusion that this coral breeds at Low Isles at about the time of new moon during part of the year, changing over to full moon for another part. There was a coincidence (but quite possibly no causal connexion) between this cycle and the behaviour of the tides, the lowest springs occurring during the winter months (May to October) at *new moon* and in *daytime*; during summer at *full moon* and *at night*.

If this interpretation of the records is correct, a change-over of the type described introduces yet *another complication into the already difficult* problem of finding any general explanation of the facts of lunar periodicity. A full account of the evidence here mentioned, together with information about the breeding of other corals and reef-animals, will be found in forthcoming reports of the Great Barrier Reef Expedition of 1928-29 (British Museum, Nat. History), vol. III, No. 8, and a subsequent report not as yet complete.

"The Case against Einstein"

NOTHING is more difficult than with good grace to protest against an unfavourable review of one's work, but again nothing is more characteristic of mawkish sentiment than to refrain on that account from asserting a point of interest to science.

In "The Case Against Einstein" I dealt with a phase of scientific thought that has received immense publicity, and that, if valid, would give for all time its own direction to physical research and mathematical investigations. This theory I have criticised in a close and minute discussion of the crucial questions in the psychological, physical, and mathematical domains, and I have advanced arguments which, true or false, are there expressed in lucidity and in rigorous form. If my reasoning is false, I have done nothing at all; if true, I have demolished the whole system of relativity and removed an incubus from the minds of students of physics all over the world. Incidentally, I have also indicated new forms of analysis which, applying to all sciences, have a direct bearing on this subject.

To this aspect of the exposition the reviewer of my book in NATURE of February 25, p. 260, has paid no attention whatever; he has devoted the very short notice accorded the book to a complaint against the "emotional" style of my writing. The emotion, consisting mainly of laughter, was directed against the tendency which I believe to prevail, even in high scientific circles, of judging a work of science, not on its intrinsic value in regard to science, but by influences, moral or immoral, which have nothing to do with the scientific merit. The "emotional" part of my book was necessary to combat the enormous popular prestige that Einstein's doctrine has acquired, so as to enable me then to focus on the essential issues involved.

Research Items

Great Bear Lake Indians. The Annual Report for 1931 of the National Museum of Canada contains an ethnographical study of the Great Bear Lake Indians of the Mackenzie District, North-West Territories, by Dr. Cornelius M. Osgood, undertaken for the Museum between May, 1928, and September, 1929. The Great Bear Lake is the focal centre of four tribes of the north-eastern Athapascans, well known in Canadian history as the Dogribs, Yellow Knives, Hares and Slaves, with the Satudene or Great Bear Lake Indians in the centre, who though politically, socially and linguistically distinct from the Hares to-day, may have become so only within the last hundred years. The tribal boundaries represent the extreme range of the tribes, but they occupy and hunt over a very small section only at any one time. Owing to climatic conditions, the food problem is insistent. It imposes a migratory habit, and at times under stress has led to cannibalism. When food is plentiful the Indians eat enormously, but no food is laid up against scarcity, as among the peoples of the Pacific coast. This in part is due to difficulty of transport, as they have to move from one place to another seasonally according to the habitat of their food supply, fishing in one place in winter, another in summer, visiting another to obtain skins for clothing and so forth. Individual effort to attain personal security, in view of the communistic habit of the tribes, is regarded as anti-social. The principal article of diet is fish, taken in winter by nets ingeniously spread under the ice. Next come moose and caribou. The moose is shot. The caribou was formerly taken by stalking, decoying, impounding, snaring and spearing. The hunting was a communal affair, initiated by the two most important men, the best hunter and the oldest man, the latter being assigned the meat for distribution. There is no individual ownership of hunting grounds. A variety of minor animals and birds was eaten. Franklin (1828) records the eating of a special kind of clay in times of scarcity or, as a chewing material, for amusement.

Archæology of the Marianas Islands. Miss Laura Maud Thompson has published a study (Bull. 100, Bernice P. Bishop Museum) of a collection of more than 9,000 archæological specimens and field notes made by Comdr. Joseph Thompson, and Mr. and Mrs. Hans Hornbostel in the Marianas, which is now in the Museum at Honolulu. The collection includes monuments, potsherds, stone implements, and skeletal remains as well as texts with translations, maps, photographs, etc., illustrative of the former culture of the Chamorro. The Marianas are of outstanding importance for the ethnology of Oceania, as they stand at the extreme north-west of the Micronesian culture area. No detailed account of this culture has previously appeared. Pure-blooded Chamorros became extinct at the end of the seventeenth century, when nearly all the males were exterminated in a religious war between natives and Spanish missionaries. Of the Chamorro culture only the language remains but slightly altered. One of the most striking features of the ancient culture is the stone monument. In Guam the stone monuments occur along the shores and in the well-watered lowlands of the interior. Double rows of upright stones are associated with caps and are accompanied by burials, potsherds, and stone and shell implements. One of the most extensively excavated sites is that of Epau, on the north-west coast. It consists of two straight parallel rows of roughly cut coral uprights, four in each row, placed in a rectangular plan with axis parallel to the shore. On the surface of the ground near each upright is a coral head-cap which apparently has fallen from its position on the upright. The uprights are about 11 ft. apart with a distance of 12 ft. between the rows. Large retaining stones support each upright. Here seventeen extended burials were found, head to south-east but facing south-west (left). They were of different ages and of both sexes. At head, chest and knees were scattered bones, potsherds, stone implements, shell scrapers and slingstones. Six skeletons had parts missing, in one instance the skull, and five showed marks of fire.

Jumping Rodents. A. B. Howell (*Proc. Amer. Acad. Arts and Sci.*, 67, No. 10; 1932) has undertaken a detailed anatomical examination of the kangaroo rat, *Dipodomys*, of the New World and of the jerboas of the Old World, with special reference to the structural modifications due to jumping and to the convergence exhibited by these two groups of rodents, which belong respectively to the families Heteromyidæ and Dipodidæ. An account of the habits precedes the anatomical description. In both groups there is some broadening of the face and a progressive weakening of the masticatory musculature, but the first of these changes is probably correlated with the enlargement of the tympanic bullæ. The neck, always short in rodents, has undergone further shortening and there appears to be also a shortening of the body with increased saltation and an increase in the strength and complexity of the back musculature associated with its use, in connexion with the hind limbs, in leaping. There is a decrease in the length and robustness of the arm and an increase in the length of the leg. The progressive elongation of the hind limb is especially marked in the pes, involving both metatarsals and digits. The breadth of the pes decreases and there is compaction of the bony elements resulting, in the most specialised forms, in fusion of the central metatarsals, and there is a tendency toward reduction and eventual elimination of the lateral digits. The perissodactyl type of foot is eventually attained, save that in the most highly specialised forms the third digit is more slender than the second and fourth, but in these cases the three middle digits tend to become grouped into a functional unit. The result of these specialisations is the assumption of a bipedal, saltatorial, digitigrade gait. The most specialised of the jerboas are far in advance of the kangaroo rats in saltatorial features. The most generalised of the Heteromyidæ are not discernibly fitted for leaping so that within this family saltatorial specialisation varies from little to much; the Dipodidæ are all highly specialised and would appear to have been exposed to saltatorial influences for a longer period of time.

Insects of the Marquesas Islands. Under the title "Marquesan Insects—I." (1932) the first of a series of bulletins dealing with collections made in the Marquesas and Society Islands has recently come to hand. It is issued by the Pacific Entomological Survey which is supported by grants from the Hawaiian Sugar Planters' Association, the Hawaiian Pineapple Canners' Association and by contributions from various sources made available by the Bernice P. Bishop Museum. The Marquesas Islands were selected for first consideration on account of the rapid floral changes known to be taking place in that group and its probable repercussion upon the fauna. Furthermore, the biology of this isolated archipelago seemed to afford valuable opportunity for zoogeographical study. Most of the collecting was done by Messrs. E. P. Mumford and A. W. Adamson and the specimens are being deposited, as worked out, in the Bishop Museum, Honolulu. Some twenty-seven papers are contained in the present part and are written by various authorities on the different groups of insects concerned. Special interest is attached to Dr. R. C. L. Perkins's descriptions of two species of weevil-like beetles of the genus *Proterhinus*, which is centred in Hawaii with but few forms known outside that group of islands. Among the termites, which were hitherto unknown from the Marquesas Islands, seven species are brought to notice, by Mr. S. F. Light, of which three are regarded as new. Dr. W. M. Wheeler writes on ants, a number of new Diptera are described by Mr. J. R. Malloch and, among other contributions, are two papers of Mr. G. F. Ferris on ectoparasites. The publication is issued by the Bernice P. Bishop Museum, Honolulu.

Periodicity in Tree Growth in the Tropics. An interesting contribution on this subject by Jean Schweizer, of Djember, Java, has appeared (*Mitt. Naturforsch. Ges. Bern*, 1932). As a result of the recent extensive vegetative propagation of *Hevea Brasiliensis*, it is now possible to compare the behaviour of clones, propagated from the same individual, under widely different conditions of cultivation and climate. The author has thus been convinced that individual differences as to time of leaf production, length of rest period, etc., are inherited characteristics although they may be modified by climate, altitude, manurial treatment, etc. He points out that the rest periods of seedlings of *Hevea* are comparatively short, and two or more crops of foliage may be developed in the year, but that the rest periods increase in length with the age of the individual, when the periodicity tends to be linked with the annual climatic cycle. An interesting observation was the effect of manurial treatment in temporarily obliterating the markedly individual behaviour shown by the different branches of the same tree as to the period of leaf production; an individuality which reappears in later years as the effect of the manure diminishes. The results of defoliation experiments are described and shown to depend upon the periodicity of growth processes at the apex. When the new crop of leaves is expanding, the growing point is forming new leaves and at this stage defoliation has little effect on the periodic cycle. Later, the growing points are forming flower buds and defoliation during this period may postpone the rest period.

Probable Meteorite Scars in Carolina. In 1930 some peculiar elliptical depressions occurring in South Carolina were photographed from the air. A careful study of the photographs showed that the origin of these 'bays', as they are called locally, presents problems of extraordinary interest. F. A. Melton and W. Schriever visited the region in the following year and their account of the observations made and conclusions reached is now published (*J. Geol.*, 52–66; 1933). The characteristic features and relationships of the depressions are (*a*) a smoothly elliptical shape; (*b*) parallel alignment in a south-eastern direction; (*c*) a peculiar rim of soil that is generally larger at the south-eastern end than elsewhere; and (*d*) mutual interference of outline. Consideration of all these and other related facts leads to the conclusion that the origin cannot be attributed to the operation of ordinary geological processes. A hypothesis involving impact by a cluster of meteorites is presented as affording the most reasonable explanation. The supposed swarm must have been large enough to possess a cross-sectional area of the order of 50,000 square miles at right angles to the direction of movement. Similar features are not known to exist elsewhere on the earth's surface. The depressions are, however, so inconspicuous to observers on the ground that even the topographic surveyors seem to have failed to see their significant characters. Aerial surveys in other coastal plains may therefore disclose the existence of similar scars that have hitherto been overlooked.

Geology of South Africa. At the meeting of the Geological Society of South Africa on November 14, 1932, Dr. S. H. Haughton recorded the results of the revised survey of the Cape Town–Stellenbosch area. The succession of the pre-Cape rocks is thus pictured: (1) Deposition of the Malmesbury sediments with local volcanic activity shown by amygdaloidal lavas, obsidians and agglomerates. (2) Accumulation of the French Hoek volcanics of the Simonsberg area, consisting of felsitic lavas and tuffs and some quartz-porphyries. (3) Formation of the French Hoek Beds: conglomerates, arkoses, grits and shales. (4) Folding and shearing of the above deposits. Intrusion of the granite, which mainly invaded the older Malmesbury beds, followed by quartz-porphyry sheets in the newer French Hoek beds. (5) Erosion, followed by the deposition of the Klipheuval sediments. (6) Movement and possible faulting of all the above. Some of the faulting, however, is post-Cape, as the Table Mountain Sandstone is also affected. It is shown that there is a marked similarity in lithological characters and sequence of events shown by the Malmesbury, French Hoek and Klipheuval beds of the Western Province with those of the Pretoria, Rooiberg and Waterberg series of the Transvaal. Dr. Haughton's paper will appear in the *Transactions of the Geological Society of South Africa*.

Steam Tables. The American Society of Mechanical Engineers, with the support of the steam power industries, has taken steps to secure greater reliability in steam tables, and the first contribution to this desired end is a paper in the February issue of the *Journal of Research* of the Bureau of Standards by Messrs. N. S. Osborne, H. F. Stimson, E. F. Fiock and D. C. Ginnings, describing their measurements of the pressure of saturated water vapour from 100° C. to 374° C.—well above the critical point. The static method is used, about 300 gm. of air-free water being enclosed in a shell of chromium-nickel-steel, the temperature of the surface of the water being determined by a platinum resistance thermometer supplemented by thermo elements of 'chromel' and 'copel', and the pressure by a piston loaded with weights. The results are given in tables, the temperature in International Centigrade degrees, the pressure in centibars, and in standard atmospheres and kilograms per square cm. for gravity 980·665. An additional table gives the temperature in Fahrenheit degrees and the pressure in lb. per sq. in. for gravity 32·174. Rates of change of pressure with temperature are also tabulated for thermodynamical purposes. None of the usual formulæ gives the pressure correctly over the whole range of temperature and the authors use a five constant formula with different constants for the ranges 100°–275° C. and 275°–374° C.

Reaction between Hydrogen and Oxygen. Hinshelwood, Moelwyn Hughes and Rolfe (*Proc. Roy. Soc.*, March) have studied the reaction between hydrogen and oxygen in a hot silver vessel. At a temperature of 650° the reaction remained fairly slow, though in a silica vessel at this temperature it would be unmeasurably fast. The explosions which occur for the silica vessel when the pressure lies within a certain range were not obtained with the silver vessel. The reaction always showed behaviour characteristic of a pure surface reaction, and the authors conclude that the silver surface has a powerful effect in breaking reaction chains which are the mechanism of a rapid reaction in the gas phase.

Study of α-Particle Groups. A recent paper from the Cavendish Laboratory deals with the analysis of α-particles by an electromagnet of new design (*Proc. Roy. Soc.*, March). The magnet consists of two bell-shaped pole pieces with a central core carrying the windings. The bells are placed mouth to mouth and an annular region of strong magnetic field is formed between their edges. A field of 10,000 gauss may be produced over an annular region 80 cm. in diameter, 5 cm. wide and 1 cm. deep with an energy of only 200 watts, and α-rays may be analysed by semi-circular focusing as in familiar β-ray apparatus. The source is placed in the annular gap, and diametrically opposite there is a small ionisation chamber connected to a valve amplifier and counting system. Successive groups of α-particles are focused on to the slit of this chamber by adjusting the magnetic field. An arrangement of search coils, fluxmeter and compensating circuit is used to measure the changes in the field. The results obtained are comparable with those obtained by Rosenblum using the great Paris magnet. The fine structure of the α-rays from thorium C is revealed, and the long-range α-particles from radium C^1 and thorium C^1 can be studied. The interest of the investigations lies largely in the relation between α-ray and γ-ray energies, and in some cases satisfactory correlations have already been made between the quantum energies of γ-rays and the energy differences between α-particle groups.

Astronomical Topics

Astronomical Notes for May. Venus is an evening star, but too near the sun for convenient observation. Mars and Jupiter are approaching each other in Leo, but do not reach conjunction until June 4. Mars is 47′ north of Neptune at 8 p.m. on May 16; this may aid observers without circles in identifying Neptune. Saturn, in the eastern part of Capricornus, may be seen after midnight; it is still too far south for convenient observation in England.

The times of disappearance, as seen from London, of four stars occulted by the moon are May 3, 10.31 p.m.; May 5, 8.57 p.m.; May 30, 10.21 p.m.; May 31, 10.17 p.m.; the magnitudes are 6·7, 5·5, 6·2, 7·0.

Two comets are within reach of moderate instruments. Comet Geddes is in Canes Venatici; an ephemeris is given in the B.A.A. Handbook. Comet Pons-Winnecke is in Aquarius; the following ephemeris is for 0^h on the days named:

	R.A.	Decl.
May 4	20^h 56^m 16^s	N. 1° 48′
8	21 17 20	N. 0 25
12	21 36 44	S. 1 1
16	21 56 32	S. 2 28
20	22 15 46	S. 3 55

It is in perihelion on May 18, at a distance from the sun of 102 million miles; this distance has increased by 6 million miles during the last revolution, owing to large perturbations by Jupiter.

To reduce to Summer Time, add one hour to all times given.

Faint Stars with Common Proper Motion. W. J. Luyten has recently published a paper describing a research that he has made with a blink microscope of plates of the region within 30° of the south pole (*Mon. Not. Roy. Astro. Soc.*, Jan.). It contains a list of stars which are concluded to be physically connected from the fact that they have common proper motions of considerable size. The paper attempts to find the probable distances and masses of the stars from a careful statistical study. There are seventy-three pairs which may be confidently taken as physically connected; a few of these had been already announced by other observers.

Two of the new pairs appear to show appreciable orbital motion in the interval of twenty-nine years between the plates; their periods are roughly estimated as 2½–3 centuries, and their parallaxes as about 0·1″ (deduced statistically, not by measurement). Both appear to be dwarf pairs, of the type of Kruger 60; they would repay visual measures with large instruments.

New Proper Motions of Stars from Bergedorf Observatory. Band 7, No. 37 of the *Bergedorf Mitteilungen* contains the seventh instalment of the "Eigenbewegungs-Lexicon". There are 3,757 new proper motions of stars (mostly faint) in the hours 4 and 5 of right ascension. Altogether 45,204 proper motions have now been published in this series. The present list has been compiled by C. Vick under the direction of Prof. R. Schorr. The declinations of the stars lie between 90° North and 1° South; they are arranged in degrees of declination, the reference numbers of the Bonn Durchmusterung being given.

For nearly all the stars observations in the present century are available; the dates of the latest observations for each star are given. Reference is made to the "Geschichte des Fixsternhimmels" for the early observations; the proper motion lists are designed to be used in conjunction with the "Geschichte". They give the magnitudes, the number of observations used for each star, and the proper motion in R.A. and declination in 100 years. No stars with less than three observations are included; generally there are four or five.

Pilot Balloon Observations at Mauritius*

THE study of the upper wind currents over Mauritius with the aid of pilot balloons was begun in July 1925, and the results obtained in the early years have been discussed by Walter and McCurdy (Geophysical Memoir No. 39 of the British Meteorological Office and Miscellaneous Publications of the Royal Alfred Observatory, No. 9 are two of the papers dealing with this subject). In Part 1 of the memoir under review is summarised all the ascents from July 1928 until December 1929 in tables giving the speed and direction of the wind mostly for steps of 500 or 1,000 metres height; and also, in the form of monthly means and frequencies, the results of recent and earlier ascents. As many as 28 ascents have reached a height of 8,000 metres and 80 a height of 6,000 metres; the general summary is taken up to 8,000 metres.

In Part 2 the results are discussed. This discussion is much more thorough than is usual in such work. It is an endeavour to "build up a scheme of the upper wind structure within the tropics and show how the scheme is modified by the seasons", to quote the authors' own words. In it they remark that meteorologists appear to be diffident in applying the geostrophic wind formula—which covers the case of air motion along a great circle—to regions within the tropics, and that their own experience has suggested to them that the isobaric chart between latitudes 5° and 25° S. is normally composed of "straight isobars", to which the geostrophic formula applies, and that the observed winds fit the isobars "at least as well, both in speed and direction, in latitude 5° as in latitude 50°".

They then proceed to derive from the geostrophic formula an expression for the height of the reversal layer between the lower easterly and the upper westerly wind currents over that part of the tropics that lies more than 5° from the equator. The formula obtained is as follows:

$$-\frac{H}{67\cdot4}\cdot\frac{P_0}{(T_h)^2}\cdot\frac{dT_h}{d\lambda}=\frac{dP_0}{d\lambda}$$

where H is the height of the reversal layer in metres, T_h is mean temperature of the air from the surface to height H, in degrees Centigrade absolute, λ is latitude, and P_0 is pressure at sea-level, in millibars.

The values given by this equation after various plausible assumptions such as the constancy of mean horizontal temperature gradients at all heights (based on the known smallness of horizontal temperature gradient at the surface over the tropical oceans, and the probability that lapse-rate varies very little) range from 17,700 metres in latitude 10° to 3,200 metres in latitude 20°.

The authors compare the theoretical figures with those found over various tropical islands, for example at Apia, Guam and Honolulu, and allowing for the seasonal disturbance caused by the shifting of the thermal equator with varying declination of the sun, obtain fair agreement on the whole, though the figures are not applicable in the neighbourhood of large land areas. The work concludes with diagrams showing the observed seasonal variation in the height of the reversal layer over Mauritius, monthly means of velocity up to 8,000 metres, and wind roses up to the same height.

The mathematical analysis in this memoir may possibly be open to criticism here and there, but a serious attempt to go beyond the descriptive stage and to relate local conditions with the general atmospheric circulation is rarely made in papers dealing with upper winds, and is particularly welcome when the region studied forms part of an immense area for which few meteorological data relating to such winds are available.

Sexual Cycle in the Rhesus Monkey

DR. CARL G. HARTMANN has recently published* an account of his detailed investigation of menstruation and pregnancy in the monkey, *Macacus rhesus*. Corner's generalisations concerning the cellular content of the vagina of the monkey are fully corroborated; the leucocyte number falls near the middle of the cycle and the number of cornified cells rises to a peak near the end of the interval. Instead of the vaginal smear method, vaginal lavage has been adopted and has proved more instructive since it enables the cells to be studied in the living condition, vitally stained with methylene blue, which also affords a ready means of differentiating the kinds of cornified cells in the vaginal lumen. The amount of desquamation from the vaginal wall can be quickly read off, after lavage, in terms of the percentage of sediment in the collecting tube. Because of the constancy and reliability of the curve of vaginal desquamation as compared with the character of the cornified cells and leucocytes recovered, the latter are no longer studied and recorded; the amount of desquamation and of uterine bleeding are the two principal factors now studied in menstruating females. When the vagina is practically free of desquamated cells the animal is at a low ebb sexually, and the uterus and ovaries are small and hypofunctional.

Forty-two females, mostly full grown, have furnished data for more than seven hundred menstrual cycles—from a few to fifty-one for the individual females. The average of four hundred cycles for twenty-two of the more vigorous females is twenty-seven to twenty-eight days, but the variations are wide. The average duration of flow approaches four to six days. Dr. Hartmann's paper adds to the literature several hundred proven cases of menstruation without ovulation; the same individual, with regular menstrual rhythm, may alternate ovulatory with non-ovulatory cycles. From an inspection of the ovaries in summer and in winter it was found that the almost complete sterility of the female Rhesus in the warm months of the year was due to her failure to ovulate. A tentative estimate of the age of puberty (the time of the first menstruation) and of maturity (the capacity to ovulate and conceive) is three and four-and-a-half years respectively.

---

* Carnegie Inst. of Washington: Contributions to Embryology, vol. 23, No. 134, August, 1932.

Precise data can now be presented on ovulation and conception-time in a menstruating primate. The most exact figures relate to nearly forty cases in which the day of ovulation was precisely determined by palpation, and information almost as exact was furnished by nearly fifty conceptions based on limited mating periods. The optimum conception day is the end of the thirteenth or the beginning of the fourteenth day. The ovaries do not necessarily alternate in ovulation; alternation is the more usual condition but the same ovary may discharge an egg twice or even thrice in successive cycles. The placental sign—due to the leakage of blood into the uterine lumen from dilated uterine glands about the site of implantation, occurred in all the cases of pregnancy observed. The sign is as infallible in the monkey as in the rat, and begins about the time the menses of the animal are due, on the average seventeen days after conception.

The span of gestation in Rhesus, based on thirty cases, is on the average 164 days, but varies with the physique of the individual—the more vigorous individuals keep the fœtus longer. A 6 per cent longer time *in utero* was associated with 26·5 per cent greater birth-weight; the latter is not considered a consequence of the former but both as a function of vigour on the part of the mother. All the mothers nursed their babies when these were viable. Seven months seems to be the usual length of time in which lactation inhibits the menstrual cycle; then cyclic manifestations increase gradually, the ovaries and uterus increase in size, but ovulation may be delayed for months although the menstrual cycle proceeds more or less regularly.

Rectal bimanual palpation of the genital organs is easy to carry out in Rhesus and gives very accurate information about the condition of these organs. It is possible not only to differentiate ovulatory from non-ovulatory cycles but also to determine the exact time of ovulation by the very evident change in size and consistency of the ovary with the collapse of the follicle. After the collapse of the Graafian follicle the corpus luteum may be felt growing from day to day and the uterus keeps pace. Pregnancy may be diagnosed by rectal palpation with relative certainty by the nineteenth day and with practical certainty by the twenty-first day. On the basis of twenty pregnancies a chart has been constructed in which the size and consistency of the uterus and the size of the fœtal head are recorded as found at each of the twenty-three and a half weeks of pregnancy, and the author states that this should enable the investigator, after a single palpation of a pregnant female, to predict the approximate date of birth. The paper is illustrated by six plates and ten figures in the text, and protocols are appended.

Fuel Research

THE Annual Report of the Fuel Research Board for the year ending March 31, 1932 (H.M. Stationery Office. 2*s.* net) refers to the incidence of the financial crisis, which necessitated a retardation of those branches of its activities which seemed less likely to produce immediate practical results.

Apart from the carbonisation plant, referred to below, considerable attention has been given to the study of tar, the most advantageous disposal of which is vital to an industry of low temperature carbonisation. Work is following two lines: (*a*) hydrogenation of the tar to produce Diesel oils and motor spirit, and (*b*) fractional distillation to recover constituents of potential value in chemical industries. The production of road tar is also being studied.

Experiments on the direct hydrogenation of coal are directed towards elucidating the influence of catalysts. Yields of motor spirit up to 145 gallons per ton of coal have been obtained, but the commercial future of the process would be dependent on the existence of a subsidy. The Coal Survey of Great Britain has now been extended to cover the whole of the national coal areas, and progress is being steadily made. This is one of the Board's most valuable tasks, for only those who have considered the selection of coal for special purposes know how limited has been the supply of authenticated data.

The Fuel Research Board has made carbonisation at low temperatures, especially in continuous vertical retorts, one of its chief studies. Cast iron retorts did not prove commercially successful but a new design of firebrick retort has been developed which, after two years' working, is considered very promising. An account of experience with them is given in Fuel Research Technical Paper No. 35, "Low Temperature Carbonisation. Narrow Brick Retorts at the Fuel Research Station" (H.M. Stationery Office. 6*d.*). A wide range of coals—even the most strongly caking —has been successfully carbonised at reasonable speeds, yielding products of satisfactory quality. The use of firebrick instead of iron has been advantageous in allowing the use of higher temperatures, which relieves the operator from many of his anxieties. The report prompts the conclusion that the plant in its evolution tends to approach existing designs of commercial carbonisation plant.

Genetic Studies on *Drosophila*[*]

THIS work referred to below is divided into three portions, dealing respectively with inverted sections of the autosomes in *Drosophila melanogaster*, with translocations between the second and third chromosomes, and with two new lines in which the X-chromosomes of the female are terminally attached to each other. The treatment is highly condensed and technical, with a wealth of new breeding data and some new interpretations.

In 1921, Sturtevant suggested that cases of reduced crossing-over which appeared only in the heterozygous condition might be due to inversion of a section of a chromosome. He has since shown that several such reducers are actually due to an inverted section—so that homologous genes do not correspond in position. In the present paper, sixteen new cross-over reducers in chromosome III are investigated. They fall into three groups and nearly all are shown to result from an inversion of a longer or shorter section. The geographical distribution of reducers in *D. melanogaster* indicates that they must arise independently and fairly frequently. In *D. simulans*, on the contrary, which has an inversion in chromosome III compared with *D. melanogaster*, this is the normal condition of the species, being found in all material collected from many different parts of the United States.

---

[*] "Contributions to the Genetics of certain Chromosome Anomalies in *Drosophila melanogaster*." By A. H. Sturtevant and T. Dobzhansky. (Publication No. 421.) Pp. v+81. (Washington, D.C.: Carnegie Institution, 1931.)

The second paper gives a genetical and cytological account of four translocations between chromosomes II and III (the long chromosomes) in *D. melanogaster*. Three of these, which arose in X-ray experiments of Dobzhansky, are called reciprocal translocations. In two of them the chromosomes both broke very close to the (central) spindle-fibre attachment, the two left halves then uniting, and also the two right halves. In the third case, the right half of chromosome III was exchanged with the terminal section of the left half of II. In another translocation, the extreme left end of II was attached to the middle of the left limb of III. These translocations are all lethal when present in the homozygous condition. In some of these translocations the pairing of the somatic chromosomes is different from that of the wild type, like regions of the chromosomes in their new positions tending to lie side by side; and in at least one, certain chromosomes are visibly different in shape from the normal. The bearing of these results on the ring formation of chromosomes in *Œnothera* is discussed.

Two lines with attached X-chromosomes are added to the two already known. They are believed to have arisen from an XX sperm. Triploidy occurred in one of these lines. and the X-chromosomes sometimes become detached, probably in oogonial cells. Three mosaic females were found, probably derived from eggs with two nuclei, as well as several mutations the genetics of which are discussed. R. R. G.

University and Educational Intelligence

Belfast.—Dr. K. G. Emeléus, lecturer in physics, who is at present in the United States with a Rockefeller fellowship, has been appointed to the chair of experimental physics in succession to Prof. W. B. Morton.

Cambridge.—W. V. Lewis, of Gonville and Caius College, has been appointed university demonstrator in geography and Dr. N. W. Pirie university demonstrator in biochemistry.

The Linacre lecture will be delivered by Prof. E. Mellanby on May 6 at 5 p.m. in the lecture room of anatomy. The title of the lecture will be "The Nervous System within the Pale of Nutrition".

London.—The following doctorates have been conferred: D.Sc. degree in biochemistry on Mr. A. G. Norman (Rothamsted Experimental Station) for a published work entitled "The Biological Decomposition of Plant Materials" (*Biochem. J.* and *Ann. Econ. Biol.*, 1929–32); D.Sc. degree in biology on Prof. R. Ruggles Gates (professor of botany at King's College) for published works entitled (1) "The Mutation Factor in Evolution" (Macmillan, 1915), (2) "Mutations and Evolution" (Cambridge University Press, 1921), (3) "Heredity and Eugenics" (Constable, 1923) and (4) "Heredity and Man" (Constable, 1929) and also about 120 scientific memoirs and papers mainly on plant genetics, cytology and human genetics; D.Sc. degree in chemistry on Mr. E. Lester Smith (Chelsea Polytechnic) for fourteen published works on the physical chemistry of soap solutions, emulsions, and the saponification of oils; D.Sc. degree in geology on Mr. B. H. Knight (University College and Chelsea Polytechnic) for a published work entitled "The Road-making Stones of Argyllshire" (*J. Inst. Mun. and City Engin.*, 1932) together with thirty-one other published works; D.Sc. degree in physiology on Mr. R. J. Lythgoe (University College) for a published work on "The Adaptation of the Eye: its relation to the Critical Frequency of Flicker" and "The Measurement of Visual Acuity" (Med. Res. Coun. Special Reports, 134 and 173); D.Sc. degree in veterinary science on Mr. S. C. J. Bennett (Royal Veterinary College) for a thesis entitled "Contagious Bovine Pleuro-Pneumonia: Control by Culture Vaccines" (*J. Comp. Path. and Therap.*, 1932); and Mr. A. W. Stableforth (Royal Veterinary College) for a published work on "Bovine Mastitis" (*J. Comp. Path.*, 1930 and 1932) and "Johne's Disease" ("System of Bacteriology", Med. Res. Coun., 1930); D.Sc. (Economics) degree on Hirendra Lal Dey (London School of Economics) for a thesis entitled "Indian Tariffs in relation to Industry and Taxation" (Allen and Unwin, 1933).

St. Andrews.—At a meeting of the University Court on April 21, a letter was read from Prof. J. E. A. Steggall intimating his retirement from the chair of mathematics in University College, Dundee, as from September 30. The Court, expressing regret at the termination of Prof. Steggall's fifty years' service in University College and its recognition of the admirable work he has done, agreed to accept his resignation and to express to him the hope that he may enjoy his well-earned retirement.

A Bayliss-Starling memorial scholarship for physiology will be awarded shortly. The annual value of the scholarship is about £120, with exemption from tuition fees, and it is tenable at University College, London. The scholar will be required to follow a course of study approved by the Jodrell professor of physiology involving a training in the principles of, and methods of research in, either physiology or biochemistry or both. Candidates for the scholarship must send their applications to the Secretary of University College, Gower Street, W.C.1, on or before May 13.

"The Crisis in Education" was recently discussed at an American Citizens' Conference convened for the purpose at Washington, and Science Service reports that, because of the value of the scientific research conducted in them and of the training for life they afford, the support of universities was strongly urged by a special committee of the Conference. Furthermore, the Conference declared that, during a period of economic stress such as that now existing, there is imposed upon all those in positions of responsibility, whether in government, industrial or cultural activity, a clear duty to promote confidence among the people in their educational institutions. A note of alarm as to symptoms of loss of such confidence is also sounded in the annual report of the Commissioner of Education.

Calendar of Nature Topics

May Sunshine

May in England is primarily the month of sunshine. Although in June the days average nearly an hour longer, the clearer skies of May almost suffice to make up the handicap, and the actual duration of bright sunshine is very nearly as great in May as in June; in some parts of the country May is even the sunnier. This characteristic of "the merry month of May" was early recognised; Shakespeare wrote: "Maids are May when they are maids, but the sky changes when they are wives." May is the last month of spring; the winds have fallen to gentle breezes, but they still blow mainly from south-west. Winds of southerly origin are generally moist, but their stratification is stable, and violent storms are rare. In June, pressure rises over the Atlantic to the west of the British Isles and the prevailing winds blow from north of west; approaching more southerly latitudes the lower layers of air are warmed by contact with the surface and tend to become unstable. Hence in June, skies become cloudier and thundery conditions begin to develop.

Swallow and Cuckoo Arrive

No migrant birds have received more general attention than these, and although consensus of opinion gives April as the usual month of first arrival in Britain, it is curious that the range within the month should be so varied. Dr. Eagle Clarke records the earliest average for the swallow as March 21 for the usual date of first arrival in England, April 6 for Scotland; Gilbert White's dates in Hampshire range from March 26 to April 20; Marwick's in Sussex from April 7 to April 27; Blomefield's in Cambridgeshire from April 9 to April 28, and the Phenological Society's average for thirty-five years works out at April 21. For the cuckoo, the corresponding average is April 26; Blomefield's average of seventeen years is April 29, his range April 21 to May 8, closely corresponding to Marwick's April 15 to May 3, less closely to White's April 7 to April 26.

Precision of Return of Swallow

One of the many interesting discoveries which the ringing method of tracing bird migration has placed beyond doubt is that swallows often return to the exact locality from which they set out in an earlier year. Dr. Landsborough Thomson has summarised the evidence from many sources. In Britain, twenty-one swallows marked as nestlings have been found again at their place of birth, seventeen in the following summer, two after two years, and two after three years, while six marked as adults have returned to the old nesting locality. Sometimes the return was extraordinarily precise, to the same porch or outhouse, sometimes to within a few miles; but occasionally a considerable distance intervened, the two greatest divergences being the return of a bird born in Stirlingshire to Yorkshire (170 miles) and of the recovery of one, born in Ross-shire, at Glasgow (125 miles) after an interval of nine years. In Hungary, von Scoöts recorded many returns of swallows and house-martins of great accuracy, and none outside a radius of two kilometres. In one instance, a bird used the same nest in six successive seasons, and a pair has been observed to keep together for three years. When it is remembered that these returns follow a double journey, to and from southern Africa, under varied conditions of wind, the precision of way-finding and the appreciation of locality take rank as outstanding wonders of bird migration.

Red Deer Shed their Antlers

Richard Jeffries states that the red deer of Exmoor shed their antlers in March, but while this is the shedding month for park deer, in general it may be said that wild stags in England cast their antlers in April and in Scotland in May. In this process, Nature seems to be in wasteful mood, for the building up of a pair of antlers weighing approximately ten pounds, largely from a material so scarce in the food of deer as lime salts, must entail a considerable physiological drain upon the stag. In less than four months, the antler will be completely formed; it will serve its purposes for the remaining eight months and then be entirely cast off.

The shedding of the antlers depends mainly upon the cutting off of the blood supply, and this is brought about by the growth of the bony tissue so that it encroaches upon the blood-vessels lying in the central mass of the antler shaft or beam. The very solid end of a shed antler represents the non-vascular tissue which, in developing, has obliterated the blood-vessels and so cut off the blood supply to the antler, causing it to become a dead structure. Then follows a process analogous to necrosis. At the junction of the antler and the process of the frontal bone upon which it rests, the bone is resorbed and an area of weakness develops, so that by rubbing its antlers against a tree or rock or even by a violent shaking of the head, the stag is able to free itself of them.

Bull Frogs Calling

By the end of April and the beginning of May, the choruses of bull frogs will be in full song in North American swamps, making noise enough to be heard a mile away and almost to deafen observers close at hand. Although frogs, as Sir J. Arthur Thomson used to put it, invented the first love song in the world, they have been able to impart a wonderful amount of variety to their croaking. The song of the Carolina toad (*Bufo terrestris*) may be no more than a slight chirp, but it has also been described, by Prof. A. H. Wright (1932), as a trill, a drone, a musical note in quality or a bass roar, to be interpreted in English (or American) as "waghrrrrrr rrrrrr"; a very different performance from that of the green tree- or 'fried bacon' frog (*Hyla cinerea*) of which the shrill, loud voice, curiously human, seems to call "grab, grab, grabit, grabit". The Carolina toad, like many of the species of *Hyla*, has a large vocal sac under its throat, and when croaking the throat is at first distended to its full capacity and the body compressed, followed by the collapse of the throat and distention of the body. The croak is of seven to nine seconds duration and is repeated at intervals of four to sixty seconds. Temperature readings during the periods of croaking varied from 58° to 88° F., but the best choruses occurred at 68° to 74° or higher. Most of the croaking was preceded or accompanied by rain, or cloudy weather, and rain appears to be the important determining factor. As the season wears on to June and July, croaking slackens in volume, and Wright's data seem to show that the later the season of chorus probably the greater the amount of rain required to give the initial stimulus.

Societies and Academies

London

Mineralogical Society, March 23. L. J. Spencer: Biographical notices of mineralogists recently deceased (fifth series). Max H. Hey: A possible source of error in the determination of symmetry from optical extinction-angles. In certain cases a small departure of a cut plate from the intended section direction may lead to comparatively large errors in the extinction angle and hence to an incorrect determination of symmetry. This is well illustrated by mesolite. Max H. Hey: Studies on the zeolites. (5) Mesolite. New analyses and X-ray studies of mesolite indicate that the correct formula is $Na_4Ca_6Al_{16}Si_{24}O_{80}22H_2O$. There is often a slight replacement of sodium by potassium, and generally an appreciable replacement of calcium by two atoms of sodium. The axial ratio has been determined by goniometric and X-ray methods. Refractive index, birefringence and optical axial angle measurements have been made. The vapour pressure has been studied by the isohydric method previously described. A number of base exchange products have been prepared and the potassium and lithium derivatives shown to be identical with those obtained from natrolite. This provides the first conclusive proof that mesolite and natrolite are, as has been commonly assumed, isostructural. X-ray photographs of mesolite are very similar to those of natrolite, but show distinct differences. The space-group is C_s'. A. E. Mourant: The dehydration of thomsonite. A study of the dehydration of thomsonite by the isobaric method. The results, obtained some years ago, are supplementary to those obtained by Hey by the isohydric method and differ from them in some respects. Dehydrated thomsonite does not absorb air. The lattice-shrinkage reaction has been further investigated. F. J. Turner: Note on the occurrence of piedmontite in quartz-muscovite-schist from the Shotover valley, western Otago, New Zealand. A description of piedmontite in schist occurring as boulders in the Shotover River. The mineral has not previously been recorded from New Zealand.

Paris

Academy of Sciences, March 13 (*C.R.*, **196**, 733-820). Charles Nicolle and J. Laigret: The conservation of various types of typhus virus in the brain of infected rats and guinea-pigs. Marcel Brelot: The problem of Dirichlet. Krawtchouk: The distribution of the roots of orthogonal polynomials. Edm. Lahaye: A method of resolution of algebraical equations. Claude Chevalley: The generation of a topological group by infinitesimal transformations. Nikola Obrechkoff: Meromorph functions which are limits of rational fractions. G. Valiron: Generalisations of theorems of Lindelöf and Phragmén. E. Crausse and J. Baubiac: Transitory regimes in a cylindrical discharge tube containing an obstacle. Albert Toussaint and Henry Giberd: The measurements of the aerodynamical characteristics of the upper and lower wings of 125 biplanes. Henri Poncin: The determination of the movements of a fluid round a cavitation. B. Kwal: The trajectories of the electrons in a longitudinal magnetic field. I. I. Agarbiceanu: The action of the magnetic field on the absorption lines of iodine (I_2). G. Bruhat and A. Guinier: Improvement of the photoelectric polarimeter: the rotatory dispersion of saccharose in the ultra-violet. With the apparatus described, the errors are less than one in a thousand up to a wave-length of 2950 A. and one in five hundred below 2950 A. René Lucas and Marcel Schwob: Anomalous dispersion in magnetic and electric double refraction. A description of the experimental results obtained with fenchone and ethyl phenylsuccinate. The anomalies observed can be explained by the hypothesis of the existence of different molecular forms in equilibrium, these forms possessing Cotton-Mouton constants or Kerr constants of contrary signs. Mlle. M. Quintin: The application of Debye's theory (formula of Gronwall, La Mer and Sandved) to solutions of copper sulphate. The formula of Gronwall and La Mer does not agree well with the facts cited: three hypotheses to account for the disagreement are considered. A. Debierne: New radioactive substances. In the course of chemical treatments of radioactive minerals, the author has noted a certain anomaly in the distribution of activity, and concludes that radium is accompanied by radioactive substances not yet characterised. G. Lejeune: Comparison of the reduction velocities of solutions of ceric and perceric salts by the sugars. Jean Grard: The osmotic pressure of solutions of nitrocellulose. Comparison of osmotic pressure and viscosity of acetone solutions of nitrocellulose before and after heating to 130° C. L. Gay and J. Soulié: A boiling point apparatus for the determination of the dew points and boiling points of mixtures of volatile liquids. Among the advantages claimed for the apparatus figured and described is the maintenance of the state of equilibrium between the vapour and liquid phases, and the uniform temperature in the two phases. Mlle. Choucroun: A correct arrangement for electrophoresis. The apparatus described can be used to concentrate colloids without alteration, and to separate a mixture of two kinds of particles unequally charged. Marcel Godchot, Etienne Canals and Mlle. Germaine Cauquil: The Raman spectrum of some cyclenic hydrocarbons. Data for cyclopentene, cyclohexene, cycloheptene and cyclooctene. B. Bogitch: Roasting sulphides, particularly nickel mattes. N. Yannaquis: The polymorphism of the paraffins. V. Kunzl and J. Köppel: The constant of the crystalline network of the rhombohedral face of quartz. Raymond Hocart: The symmetry of boracite and X-rays. Jacques de Lapparent: The signification of the granulites of Brittany and the genesis of the crystallophyllian. Raymond Furon: The discovery of the fossil-bearing intrusive Cenomanian and new Turonian deposits in the Niger Colony (geological material collected by M. Auguste Chevalier). Marcel Thoral: The discovery of new fossil-bearing deposits in the Potsdamian and lower Arenig of the Montagne Noire. Mlle. G. Homery: The magnetic declination on the whole of the globe. Ch. Maurain: Remarks on the preceding note. Ladislas Gorczynski: The part of the solar radiation diffused by the celestial vault in the total insolation. L. Eblé and G. Gibault: The values of the magnetic elements at the Val-Joyeux station (Seine-et-Oise) on January 1, 1933. Charles Killian: Ecological researches on the seasonal fluctuations of chlorophyll assimilation in plants of the Algerian maquis. Raoul Lecoq: The rôle of the B vitamins in the utilisation of the glycides by the organism of the pigeon. The comparative action of levulose, glucose, galactose and of some dissacharides (holosides) incorporated in balanced regimes, rich in lipides. P. Cappe de Baillon: The formation of the egg-shell in the Phasmidæ. Mme. Louise Nouvel: Casting the shell of *Leander serratus* affected with the parasite *Bopyrus Fougerouxi*. The growth and casting the shell in *Leander* is in no way influenced by the presence of the parasite. J. André Thomas: The pure culture of the umbilical vitellin syncytium of the embryo of the fowl. The first stages. Mlle. A. Kramer: Contribution to the study of the heterosides of *Philyrea latifolia*. Two heterosides have been extracted from the bark of *Philyrea*, one named philyroside identical with the philyrine of Carboncelli and of Bertagnini and Luca, another proved to be identical with syringoside (syringine) isolated from various plants of the Oleaceæ. C. Charaux and J. Rabaté: Contribution to the biochemical study of the genus *Salix*. Isosalipurposide. H. Bordier: The continuity of Merget's phenomenon.

SYDNEY

Linnean Society of New South Wales, Nov. 30. H. L. Jensen: Contributions to our knowledge of the Actinomycetales. (4) The identity of certain species of *Mycobacterium* and *Proactinomyces*. A number of organisms previously described as species of *Mycobacterium* were found, on account of their definite mycelial growth in the initial stages of their life cycles, to have their proper place in the genus *Proactinomyces*. *M. agreste* Gray and Thornton and *B. mycoides corallinus* Hefferan must be regarded as one species, *P. corallinus*. *M. salmonicolor* den Dooren de Jong is closely related to this and should be called *P. salmonicolor*. *M. opacum* den Dooren de Jong and *M. crystallophagum* Gray and Thornton are identical; this species should be called *P. opacus*. *M. erythropolis* is closely related to this; its proper name should be *P. erythropolis*. *Microbacterium mesentericum* Orla-Jensen showed a very distinct mycelial growth and should be called *P. mesentericus*. T. G. B. Osborn, J. G. Wood and T. B. Paltridge: The growth and reaction to grazing of the perennial saltbush, *Atriplex vesicarium*. An ecological study of the biotic factor. The root system is extensive and superficial, with deciduous feeding roots. The leaves, which are non-cuticularised with a high salt content, are able to absorb water vapour from a nearly saturated atmosphere. The plant is, indeed, dependent for a portion of its water upon moisture absorbed from the air. With continued drought and loss of vegetative vigour it passes through states of wilting, defoliation and anabiosis. Moderately heavily grazed saltbush is more vigorous during a drought period than lightly grazed bush or bush that is not grazed at all. Saltbush is most profitably utilised under a system of moderately heavy intermittent grazing. J. G. Churchward: The geographical distribution of *Tilletia* species on wheat in Australia in 1931. Two species of *Tilletia*, namely, *T. tritici* and *T. levis*, are widely distributed and prevalent in most of the wheat-growing areas of Australia. This fact has an important bearing on the development of disease-resistant varieties, as it has been shown by Johnston (1924), Kienholz and Heald (1930), and Holton (1930), that varieties do not necessarily react in the same way to the two species of bunt. I. M. Mackerras: The Australian species of *Graphomyia* (Diptera, Muscidæ). One species of *Graphomyia* from North Australia is described as new. G. A. Waterhouse: Australian Hesperiidæ (3). New subspecies are described as follows: two of *Trapezites symmomus*, one of *Netrocoryne repanda*, and a new form of *Euschemon rafflesia*.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 18, 677–730, Dec. 15, 1932). Barbara McClintock: A correlation of ring-shaped chromosomes with variegation in *Zea mays*. Diminution in size or loss of the ring chromosomes was observed in eight cases, seven of them the progeny of X-rayed pollen. This leads to variegation if the ring carries a 'genetic marker'. M. Biot: Critical torsional oscillations of a rotating accelerated shaft. A theoretical discussion, assuming the forces applied to the shaft have a part (a moment of constant amplitude per unit length) varying with a frequency proportional to the angular velocity, and neglecting damping. Benjamin Kropp: The crustacean chromatophore activator and the gonads of the rat. Active extract from the eye-stalk of *Palæmonetes*, though like pituitrin causing melanophore movements in fishes and tadpoles, has no observable effect on the gonads of rats. Matilda Moldenhauer Brooks: The penetration of *m*-bromo-phenol indophenol and of guaiacol indophenol into *Valonia ventricosa*. Both these dyes penetrate the cells and are found inside in the reduced form. Kenneth V. Thimann and James Bonner: Studies on the growth hormone of plants. (2) The entry of growth substance into the plant. Curvature of oat coleoptiles is proportional to the concentration of growth substance supplied in solution in agar blocks. A theoretical discussion brings Went's observations, which suggested that the amount of growth substance was the effective factor, into line with the new results. Hudson Hoagland: Impulses from sensory nerves of catfish. Electrical responses were recorded from lateral line nerves, spinal nerves supplying skin of flank, and branches of the facial supplying tastebuds of lips and barbels, after mechanical, thermal and chemical stimulation of the receptors. The lateral line nerve appears to be in a state of continuous spontaneous activity and the individual neuromasts can be synchronised by a tuning fork. The system, contrary to the facial and spinal nerves, seems to be a thermal receptor. Karl T. Compton: Accommodation coefficient of gaseous ions at cathodes. An ion entering the positive ion space charge sheath round a cathode acquires a certain momentum and strikes the cathode; after neutralisation, it may leave the cathode with appreciable energy, a point hitherto neglected. Of the impulse given to the cathode, part is exactly compensated by the mutual pull of cathode and ion during approach and the remainder alone contributes to the pressure on the cathode. The effect is described in terms of the 'accommodation coefficient' used to give the energy transfer of gas molecules at temperature T_1 striking a surface at temperature T_2 and leaving at temperature T_2. Gustav A. Hedlund: Recurrent geodesics on any closed orientable surface of genus one. W. J. Trjitzinsky: (1) The general case of integro-Q-difference equations. (2) A property of indefinitely differentiable classes. H. R. Brahana: Operators of order p^m in the group of isomorphisms of the Abelian group of order p^n and type 1, 1, . . . Marston Morse and S. B. Littauer. A characterisation of fields in the calculus of variations. Dealing with a geometric characterisation of focal points and conjugate points in n-space for $n > 2$.

Forthcoming Events

Monday, May 1

National Institute of Industrial Psychology, at 6—(at the London School of Economics, Houghton Street, W.C.2).—C. B. Frisby : "The Internal Economy of the Office".

Royal Geographical Society, at 8.30.—A. V. Coverley-Price and Miss M. McKinnon Wood : "Professor Gregory's Expedition to Peru".

Tuesday, May 2

Institution of Civil Engineers, at 6.—(James Forrest Lecture.) Sir Harold Hartley : "Recent Advances in the Application of Chemistry to Engineering".

Wednesday, May 3

Eugenics Society, at 4—(at the rooms of the Linnean Society, Burlington House, London, W.1).—Annual General Meeting.

Bedford College for Women, at 5.15.—Prof. E. A. Bott : "Principles of Critical Analysis in Relation to Modern Psychology" (succeeding lectures on May 4 and 5).

Royal Society of Arts, at 8.—Prince Ginari Conti : "The Natural Steam Springs of Tuscany and their Industrial Application".

Thursday, May 4

Huxley Memorial Lecture, at 5.30—(at the Imperial College of Science and Technology).—Prof. H. E. Armstrong : "Our Need to Honour Huxley's Will".

University of London, at 5.30—(at the Institution of Civil Engineers, Great George Street, Westminster, S.W.1).—R. Freeman : "Long Span Bridges".

Friday, May 5

London School of Hygiene and Tropical Medicine, at 3.15.—Dr. E. L. Middleton : "Industrial Hygiene" (succeeding lectures on May 12, 19, 26 and June 2).

Chemical Society, at 5.15—(joint meeting with the University College of North Wales (Bangor) Chemical Society at the Memorial Science Buildings, Bangor).—Prof. C. S. Gibson : "The Chemistry of Gold".

Geologists' Association, at 7.30—(in the Architectural Theatre, University College, Gower Street, W.C.1).—Sir Albert E. Kitson : "A Geological Reconnaissance through Kenya, British East Africa".

Saturday, May 6

University of Cambridge, at 5—(in the Anatomy Lecture Room).—Prof. E. Mellanby : "The Nervous System within the Pale of Nutrition" (Linacre Lecture).

Entomological Society of London, May 3–4.—Centenary Celebrations at rooms of the Royal Geographical Society and Lancaster House, St. James's, S.W.1.

Electrical Association for Women, May 3–5. Eighth Annual Conference to be held at Birmingham. President : Dame Ethel Shakespear.

Iron and Steel Institute, May 4–5. Annual Meeting. W. R. Lysaght—Presidential Address.

The Utilisation of Coal*

THE British Science Guild has now published the full text of the papers delivered, and a verbatim account of the subsequent discussion, at the symposium on the utilisation of coal, held at the Royal Institution on March 27, a report of which appeared in NATURE of April 1. Members of Parliament; some of the largest trade unions; interested Government departments; coal-getting and coal-distributing organisations; gas, oil and chemical interests; scientific and technical institutions, were all well represented, a fact which should encourage the Council of the Guild to arrange more meetings of this kind on subjects of national importance and where scope is given for the expression of varying opinions and differing interpretations of available data. It is the object of the British Science Guild to promote the application of scientific method and results to public affairs, and probably there is no surer way of appealing to the public imagination than by providing facilities for experts to express in terms intelligible to the layman the effects of their investigations on industrial aspects of national progress.

While, however, we must congratulate the British Science Guild on arranging a symposium on a subject of such interest as to prevail upon so many busy and distinguished persons to forsake all other duties to be present, we must confess to a feeling of disappointment that the expert protagonists of coal and oil and gas, and most of those authoritative experts who contributed to the discussion, made such poor use of the exceptional opportunity afforded them. Engineer Rear-Admiral Scott-Hill's paper on "Coal and Sea Transport" was the only contribution of real merit, noteworthy alike for its substance, the impartiality with which he assessed the relative advantages of coal and oil as fuels for the mercantile marine and the navy, and the suggestions made for the extended use of coal. The paper by Mr. Stephen Lacey, of the National Gas Council, on "Development of the Use of Gas", exhibited the same regard for accuracy but it presented no new features and dealt far too briefly with either the possibilities of high pressure gas cylinders for lighting and power purposes, or those of high pressure gas mains for distributing heat, light and power direct from coal-fields to the towns and other industrial centres, of which the practical possibilities have already been demonstrated in Germany.

---

* "A Symposium on the Utilisation of Coal." Pp. 46. (London: British Science Guild, 6 John Street, Adelphi, W.C.2.) 1s.

Capt. Acworth and Mr. A. C. Hardy have been in the lists before as protagonists of coal and oil respectively. It is unfortunate that both these experts preferred to indulge in polemics instead of providing the audience with complete comparative data from which the experts and laymen present could have drawn their own conclusions. In his enthusiasm for a 'Back to Coal' movement Capt. Acworth made assertions to which even a back-bench politician would hesitate to commit himself. We do not question the fact he gave that Great Britain's annual output of coal decreased from 287,000,000 tons in 1913 to less than 220,000,000 tons in 1931. But his paper contained no justification for his conclusion that "considerably more than 67,000,000 tons of British coal has thus been replaced by oil". Again, his statement that since 1913 "the change over on sea and land from coal to oil has adversely affected our national trading balance by £960,000,000" should not have been made without his audience being informed of the statistics on which he based this estimate.

Capt. Acworth asserted also, in support of his argument, that the oil industry has been subsidised at the expense of the British taxpayer, that "In this country alone £1,600,000,000 has been expended in making the roads fit for motor-traction", a total which obviously includes expenditure on making and upkeep of roads which would have been incurred if the motor-car had never been invented. Although Capt. Acworth believes that "low temperature carbonisation has a considerable future if the solid fuel is treated as the main product", he discounts the possibility of the mercantile marine and navy obtaining their supplies of oil by this process of extraction from home-produced coal and dismisses as fantastic the economic practicability of obtaining oil from coal by the hydrogenation process.

Mr. Hardy was guilty of at least two important omissions in his own contribution, both of which unfortunately passed without comment. In the first place he made no reference to the decision of one of our greatest ocean liner companies to experiment with pulverised coal and colloidal fuels; and in the comparative figures he gave of fuel consumption by coal-burning, oil and Diesel ships, he made no reference to the relative costs of coal and oil and the running expenses of the three different types of marine engines. It is surprising also that he did not refer at all to the possibility of obtaining our oil supplies from our own coal. Curiously enough, Mr. Stephen Lacey made no mention of the part played by the gas companies in connexion with home-produced hydrocarbons. Neither did he deal with the economics of the other by-products of coal in relation to the coal-gas industry.

Mr. Hardy fell into the grave error of assuming that any body which offers the expert exponents of competing industries an opportunity to inform public opinion on recent advances in the fields of enterprise in which they are interested, necessarily subscribes to their views or vouches for the accuracy of the data which they use in their papers. *Petroleum Times*, in its issue of April 1, made the same error. Commenting on Capt. Acworth's paper, it said: "rarely, if ever, can coal and oil technologists have listened to so many mischievous and distorted statements"; and added, "we are left with a deep conviction that the British Science Guild has lowered its reputation by allowing such distortion to pass out under its name". The fact is, the British Science Guild provided a platform for a controversy which is of vital interest to the nation, and it was evident from the company which assembled that pains had been taken to ensure that in the audience were experts who could, if they had chosen, challenge the accuracy of the data given and comment on the conclusions drawn, by those who read papers.

Unfortunately, however, most of the experts who contributed to the subsequent discussion were apparently more concerned to prove that the coal-owners and distributors are largely responsible for the present unsatisfactory situation of the coal industry than to enlighten the audience on the relations between the coal industry and the oil and the chemical industries. The dyestuffs industry was not even mentioned: and only casual reference was made to low temperature carbonisation and hydrogenation of coal, although these two processes have been the subject of comment and controversy for years past. This is a great pity, for there are very many people in Great Britain who wish to be informed on the economics of oil from coal projects, more particularly as seventy per cent of our imported oil supplies come from the United States of America, to which we are already heavily indebted and to which we are unable to sell much in exchange owing to the prohibitive tariffs.

Civilisation and War

They that take the Sword. By Dr. Esmé Wingfield-Stratford. Pp. xv+422. (London: George Routledge and Sons, Ltd., 1932.) 12*s*. 6*d*. net.

ONE of the principal arguments of this book is that the next war on the grand scale will mean the complete annihilation of modern civilisation; a phrase easily uttered, but the terrible significance of which is not easily apprehended. Probably by the cynics and pessimists among us it will be so little apprehended that this particular argument will make no very profound or soul-stirring appeal. They will at once agree that our civilisation, such as it is, deserves no other fate, which is, in any case, inevitable. This, however, is a question of fundamental philosophy or historical interpretation which is perhaps beyond our present scope, and, as the author of this powerful denunciation of war in all its aspects has done, it is taken for granted that civilisation must be saved.

If reasoned argument and moving eloquence alone could abolish war, then war would long ago have been abolished, or if not, this book would surely finish the perfect work. As a reasoned statement of the case against war these scholarly and persuasive pages could scarcely be surpassed in strength and lucidity and cogency of argument, in splendid wealth of apt illustration and historical lore, and in devastating logic against the folly and madness of war from every point of view; or, from nearly every point of view: there are one or two aspects which, as noted later on, do not appear to us to be sufficiently treated. No rational mind in its calm moments could for one instant dispute or deny the truth, wisdom, broad-minded charity, and profound scholarship breathing in every page. In both breadth of learning and scope and in depth of philosophical reasoning the book is remarkable, though the author's attitude towards Old Testament Hebrew history may be unpalatable to some; and alike for the general reader and the student of history the keenest interest is sustained to the very end, despite its more than four hundred closely printed pages.

To the man of science the work will be of particular interest. Dr. Wingfield-Stratford's main thesis indeed is that, chiefly owing to scientific progress, the fabric of civilisation tends to become ever more liable to fatal injury with increasing development in extent and complexity; the powers of destruction and self-destruction conferred on mankind by science are continually increasing; and the combination of these two tendencies must mean annihilation (p. 378). Whilst apparently accepting the evolutionary doctrine in the main, the author nevertheless holds that "progress in evolution is a progress in unity, in co-operation, in the membership of each in all, in the fulfilment of every lesser individuality in a greater, until God, the supreme and ultimate unity, shall be all in all". There is no basis in fact for the so-called economic theory of enlightened selfishness—which was often extremely dark and unenlightened, expressing itself in cut-throat competition. The respective merits of competition and of co-operation in all their manifold complex forms are vital factors in any discussion of war; and a growing realisation of international dependence and the advantages of co-operation as against trade war is one of modern civilisation's hopes, though unfortunately, at the moment, this realisation is more in theory than in fact.

The alleged Darwinian necessity of a struggle *à outrance* for survival has by no means been universal; and the author brings all the weight of his wide historical knowledge in support of this view, as also against the popular fiction of a pugnacious and ruthless club-wielding caveman. Thence he argues against the supposed inherent love of fighting in human nature. Even if this latter propensity be real it could play no part in, nor derive any satisfaction from, the nameless horrors of modern mechanised warfare. Its proper sphere is the boxing ring or other place of sport, and it is as little intended for the shambles of a modern battlefield as a high-spirited dog is intended for the abattoir of the butcher. Courage, strength, skill, stand as little chance in the one as in the other.

Sir Norman Angell long ago showed the great illusion of war from a material point of view. This needs no further emphasis in these days when even victory brings no gain, but irreparable loss. Dr. Wingfield-Stratford now, with masterly analysis and illustration, in his chapters on the mind and soul of the soldier, brings into startling visibility the repressing and stultifying effect of military preoccupations on the mentality of the professional soldier, and, more generally, the tragic bar to national progress and culture formed by diversion of so much of the nation's energy into military channels. He is particularly severe against Napoleon and other "conquering heroes", whose reputations for real greatness are shattered in this book with the enthusiasm of an iconoclast.

It is not, of course, possible to follow the author wholeheartedly in every point he endeavours to make; there will be dissent from the sweeping condemnations contained in the chapters just referred to on the professional soldier's mentality. Some exceptions are indeed admitted by the author himself. In any event, his remarks on the attitude of the military mind towards scientific advance in the arts and mechanised means of war will be read with marked interest. As a general rule he thinks the military mind is too low-grade and undeveloped to understand or appreciate scientific help.

Then again, despite his breadth of treatment, touching, it would seem, every possible aspect of a highly complex subject, the author does not appear to treat very adequately of what may be called defensive wars. There have been, of course, in the past and may well be again in the future, cases of unprovoked assault in which the attacked nation could do no other than defend itself. Also should not the weak nation be protected against the strong and ruthless aggressor? These and many other difficult matters of a highly controversial kind necessarily go to the heart of the *raison d'être* of the League of Nations, its policy and methods.

Dr. Wingfield-Stratford is mainly concerned in stating the case against war: he does not say a great deal as to practical measures for ensuring peace, except world-wide and enthusiastic support for the League and a change in spirit. It should, no doubt, be sufficient for all reasonable men to realise the full significance of another world-war to ensure the complete abolition of war. Unlike all wars of the past, the next war may include the exposure of the entire civilian populations to the horrors of air-bombing and poison gas on a scale not yet known or realised. Is further appeal needed? Civilisation would indeed be utterly destroyed amid every circumstance of unmitigated horror and terror, and the fate of the world in such case could scarcely be depicted in too lurid colours. The most powerful safeguard to ensure world peace is, in the author's opinion, a change in spirit worked by a full and complete return to the teaching and practice of the founder of Christianity.

The Naturalist and the Country Side

(1) *The Common Earth.* By E. L. Grant Watson. Pp. xi+148. (London: J. M. Dent and Sons, Ltd., 1932.) 5*s*. net.

(2) *The Trail that is Always New.* By Willoughby P. Lowe. Pp. xix+271+22 plates. (London and Edinburgh: Gurney and Jackson, 1932.) 16*s*. net.

(1) THIS little book is made up of essays on English country life, which were broadcast in 1931–32. They are pleasantly written observations on the seasons, on animal, bird and insect life, and on the life-history of a typical old peasant. Such lectures do not aim at the revelation of anything new, but we take it were given with the object of arousing the interest of the townsman, and of the otherwise unobservant person, in the many attainable delights of a lover of the country.

The author tells his stories of animals and of his country rambles so attractively, that the reviewer regrets his occasional excursions into philosophical surmise, and agrees with his assertion that feelings aroused by observation of Nature cannot be put into a few simple words. Thus after about two pages on the starlit sky, we read: "As we gaze, the persuasion grows that all these marvels of the sky are under-arched and upheld by the no less potential vastness of mind which perceives them." Here surely the words convey no clear meaning or feeling at all. In describing autumn, the author emphasises the steps taken in Nature to ensure the fall of the leaf, etc., and then remarks: "In this widespread seasonal act of deliberate dying, nature is saying something with no uncertain voice. It is worth listening to." Surely Nature is saying that the fall of the leaf is no more a deliberate act of dying than is the moult of a bird, or perhaps the hibernation of an animal.

Mr. Grant Watson has the power of sharing his pleasure in birds and beasts with his reader. We know that he has respect and affection for wild life, so that his last chapter—on Wicken Fen—gives us the more surprise. He refers to "these good days when one could see as many as twenty sheets on the fen at night with lamps in front of them"—these being provided by one Solomon Bailey at a cost of half a crown each, with the object, be it noted, not of the observation of wild life, but of the ruthless slaughter of as many rare moths as possible. He himself thus captured the rare *palustris* which only appears every seven years or so, and then only in ones and twos for one week in June.

The reviewer hoped against hope that a word of appreciation for the work of the National Trust in preserving the wild life would have shown that the words "these good days" were writ "sarcastic-like". Entomologists, naturalists, botanists, all are welcomed to Wicken, without the half-crowns, provided that they come to *learn*, not to destroy, to observe and commune with Nature rather than to kill her children for pecuniary gain as so often in "these good days".

(2) Mr. Willoughby Lowe was bred in Lincolnshire, but in 1888, when only sixteen, joined a brother in Colorado. Here he lived for nine years, collecting, communing with Nature and learning that reliability and assurance of self to which he many times afterwards owed his life. It was a wild, open country and no better training ground can be imagined with its plains and heights, its summers of drought and its winters almost glacial. In 1912 commenced an honourable connexion with the British Museum, the collections of birds and mammals of which he so greatly enriched.

Many lands were visited, even Siam and the Philippines, but perhaps the reader will be most interested in the repeated investigations of African life. After a trip in East Africa in 1913, he travelled from Lake Rudolf to the Nile through waterless and dangerous country, from which the party was fortunate to emerge. When returning home, Lowe met Abel Chapman, another fine naturalist, with whom he collected afterwards in the Sudan. The biggest venture was in 1920 with Admiral Lynes to Darfur, where they were detained owing to the rebellion of 1921, the expedition extending over eighteen months. The haul here was 365 species of birds and 62 mammals, many hitherto undescribed. The west coast of Africa was visited many times, and extensive collections were also made in Madagascar, in parts the wildest of countries.

Then "farewell" to the reader without fuss for the trail is calling, "this time to the borders of China". Perhaps later Lowe will reflect on his life, all he has time to add here being a few health hints which we summarise as recommending warm baths, as little exposure to the sun and insect bites as possible, equal parts of penny royal and olive oil to deter mosquitoes, boiled water, 5 grains of quinine per day, and *one* peg of whisky but "never before sundown".

We confess that we did not expect to enjoy the story of a collector's expeditions, but Mr. Lowe has written such a simple, unaffected narrative that he has disarmed us. He is primarily a naturalist as indeed the successful collector must be, and his tale excited us in the same way as did Wallace's "Amazon", more than forty years ago. The science of both these 'travels' consisted of the facts observed, and the 'how, when and why' of the pseudo man of science, usually mere guess-work, is eschewed. All naturalists will like to have this book on their shelves.

Relativity and the Structure of the Universe

The Expanding Universe. By Sir Arthur Eddington. Pp. ix+128+2 plates. (Cambridge: At the University Press, 1933.) 3*s*. 6*d*. net.

SIR ARTHUR EDDINGTON'S skill as a writer is well known to-day. He makes effective use of it in this brilliant exposition of the theory of the structure of the universe from the point of view of the theory of general relativity. The observational problem to be discussed is becoming familiar to all scientific workers. Our galaxy is apparently surrounded by a cloud of other galaxies, the spiral nebulæ, which appear to be evenly scattered throughout space. This cloud, moreover, does not seem to have a boundary. The spectral lines of the light emitted by these nebulæ exhibit a shift towards the red end of the spectrum which increases proportionately to the distance of the nebula concerned. By means of the Doppler effect in the wave theory of light, this observed red-shift is interpreted as a velocity of recession. The speeds so found are enormous: the most recent determination is 24,000 km./sec. for a faint cluster of nebulæ in the constellation Gemini. With this interpretation of the red-shift, we are evidently dealing with a material system which is certainly expanding and is also boundless.

Sir Arthur Eddington points out that the existence of such a system of material particles (the nebulæ) which has no boundary and in which each particle is uniformly surrounded by all the rest, implies that the system occurs in a curved and closed space. If each particle sees all the others moving away from it with velocities proportional to their distances, the space must be expanding as well as closed. Of course, it is always open to those who have preconceived ideas as to what space 'ought' to be, to represent this curved space as 'flat' by introducing appropriate distortions, just as the curved surface of the earth may be mapped on a flat plane. But the relativist will not feel called upon to do this. The equations of general relativity not only expressly allow for the possibility of using curved spaces, but also contain the cosmical constant $\lambda\ (> 0)$ which suggests that such spaces may be 'expanding'. Roughly speaking, the presence of the 'λ-term' in the equations is tantamount to the assumption that, in addition to the gravitational attraction between particles of matter, there exists a universal repulsive force which will cause a general scattering of any collection of particles provided it can get the upper hand of their mutual attractions. In the physical universe this is supposed to have happened, with the result that all the nebulæ now appear to be receding from us.

It is possible to imagine a state of affairs in which, throughout the whole universe, gravitation and repulsion just balance one another. This is the so-called Einstein universe. Space is then spherical and the condition is one of unstable equilibrium, so that the slightest disturbance in the appropriate direction will start an expansion. Sir Arthur Eddington considers that physical space started from such an equilibrium state. This has the advantage, amongst others, of giving the longest time-scale yet proposed (some 10^{10} years) since the expansion effectively began.

The last chapter of the book is devoted to Sir Arthur Eddington's own investigations on the border-line between relativity and quantum mechanics. The wave-equation for an atom gives the size of the latter. Sir Arthur believes that a 'length' at any point in space must be relative to the radius of curvature of space-time at that point. Hence the wave-equation must contain this radius. It must also involve something representing the action on the atom of the rest of the universe. It is then possible to deduce, from the constants occurring in the wave-equation, the value of the velocity of recession of the spiral nebulæ and the number (10^{79}) of the protons and electrons in the universe. These results are, as yet, not universally accepted but there can be little doubt that they point towards the goal so long sought after: the all-embracing theory which shall account for both the microscopic and the macroscopic phenomena of Nature. G. C. McV.

Short Reviews

Indian Caste Customs. By L. S. S. O'Malley. Pp. ix + 190. (Cambridge: At the University Press, 1932.) 6*s*. net.

MR. O'MALLEY quotes a remark by Lord William Bentinck, when the prohibition of suttee was under consideration, that the question was not what the rite was, but what it was thought to be. His own account of Indian caste customs is quite in this spirit. His object is to show how the caste system works in the everyday life of India, without entering into any inquiry as to origins, or the origin of specific castes and groups except in so far as present conditions are thereby affected. He writes for those whose knowledge of caste is at best superficial, and shows how it works in the spheres of social position and intercourse, marriage and morals, internal regulation and external control, food and drink, and occupations.

A chapter is devoted to the Untouchables, and one to modern tendencies, in which it is pointed out to what extent caste regulations are now breaking down. Here, in view of the public for whom the author writes, even more stress might have been laid upon the weight of conservatism in the rural population, which constitutes nine-tenths of the whole Hindu population. He wisely emphasises the strength of feeling within the castes for its preservation as the fitting, and indeed to them the only possible, ordering of society which would maintain social prestige. This applies even to the Untouchables. This is an aspect of the problem upon which Mr. O'Malley, as an ex-census officer, is well qualified to speak. The advantages and disadvantages of caste as a social, political and ethical factor are balanced with judgment.

It is to be regretted that this book was not published earlier by two or three years; as it is, it will give the public a juster estimate of the difficulties which still have to be faced in India.

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. By Dr. J. W. Mellor. Vol. 12: *U, Mn, Ma, Re, Fe (Part 1).* Pp. xiii + 944. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1932.) 63*s*. net.

THE new volume of "Mellor" includes the elements uranium, manganese and its recently discovered homologues, and iron. The chapters dealing with the first two elements do not call for special comment, although it may be noted that triangular diagrams are used extensively to illustrate the properties of ternary alloys of manganese and that the spectrum of the element is recorded in unusual detail. It is, however, of interest to note that the homologues of manganese already occupy 17 pages, including more than 1½ pages of references, nearly all dating from 1929, when rhenium was first isolated in substantial quantities.

The chapter on iron differs from any that have appeared hitherto, in that nearly half a volume is now devoted to pure metallurgy. The compounds of iron are therefore held over to a subsequent volume. The thoroughness with which the literature has been searched is indicated by 17 pages each of references to the history of iron and to its extraction from its ores, and 30 pages of references to its occurrence. Greater interest will be found, however, in the sections on the allotropes of iron, its microstructure and crystalline form, the iron-carbon system, etc., where questions of wide general interest are discussed and illustrated with photomicrographs, equilibrium diagrams, and other figures, of which the chapter contains a total of no less than 178. Whilst, therefore, the chapter on iron will maintain (and may even enhance) the reputation of the book as an encyclopædic guide to the literature, its particular character makes it much more readable than some of the other chapters.

Théorie de la quantification dans la nouvelle mécanique. Par Prof. Louis de Broglie. Pp. xxviii + 250. (Paris: Hermann et Cie, 1932.) 70 francs.

THE attention of theoretical physicists ought to be directed to this volume, in which Prof. Louis de Broglie develops the general theory of 'quantification' and elaborates the exposition given in his "Introduction to the Study of Wave Mechanics". Instead of following the method of matrices associated with the names of Heisenberg and Born, or Dirac's method using a non-commutative algebra, he systematically proceeds from the point of view of undulatory mechanics. His treatment approaches that employed by Weyl at the beginning of his work on group theory and quantum mechanics.

The first part of the book is introductory and deals with the general principles of wave mechanics. After discussing the indispensable mathematical preliminaries he proceeds to the general theory, which leads to the prediction of the quantified values of any mechanical magnitude whatever, and the respective probabilities of these quantified values. He attaches importance to the study of the first integrals, which he regards as one of the essential parts of the new mechanics. He claims to have given a logical and consistent treatment of modern quantum theory, which appears so strange to those who are familiar only with classical conceptions.

Collected Papers of Charles Sanders Peirce. Edited by Charles Hartshorne and Paul Weiss. Vol. 1: *Principles of Philosophy.* Pp. xvi + 393. 21*s.* net. Vol. 2: *Elements of Logic.* Pp. xii + 535. 31*s.* net. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1932.)

THE authorities of Harvard University are to be congratulated for their publication of the papers and notes left by Charles Sanders Peirce. A master mind and a pioneer in philosophical inquiry, Peirce had never an occasion of publishing a standard work embodying his views. So that the editing of his papers is in itself a feat which deserves the praise and gratitude of all scholars. We would do little justice to the philosophical vision of Peirce in estimating his work on the strength of the first two volumes, out of a series of ten, which are to be published. It will suffice at present to indicate the wide range of topics touched upon in the present volumes: the method of science, the classification of the sciences, the logic of mathematics, the categories, the character of logic, speculative grammar, critical logic, and the theory of probable inference. T. G.

An Introduction to Analytical Psychotherapy. By Dr. T. A. Ross. Pp. vii + 203. (London: Edward Arnold and Co., 1932.) 10*s.* 6*d.* net.

DR. ROSS is to be congratulated on a very readable book. He gives a good account of the unconscious which he considers must be assumed to exist. Although the author, to a large extent, is a very staunch supporter of Freud, he is very honest in his appraisal of his methods, and candidly admits that suggestion must in any analysis play a very important part. This we consider very important and very true.

The author is not inclined to accept a fixed symbolism for any interpretation of dreams. He rightly points out how Freudian symbolism carried to undue limits may give interpretations which are undoubtedly false; dream interpretation is not so straightforward as some good Freudians would have us believe.

We cannot agree with the author that Adler does not appear to have made much contribution to psychotherapy. There are many who do not accept Freud or Jung, but are willing to accept Adlerian ideas.

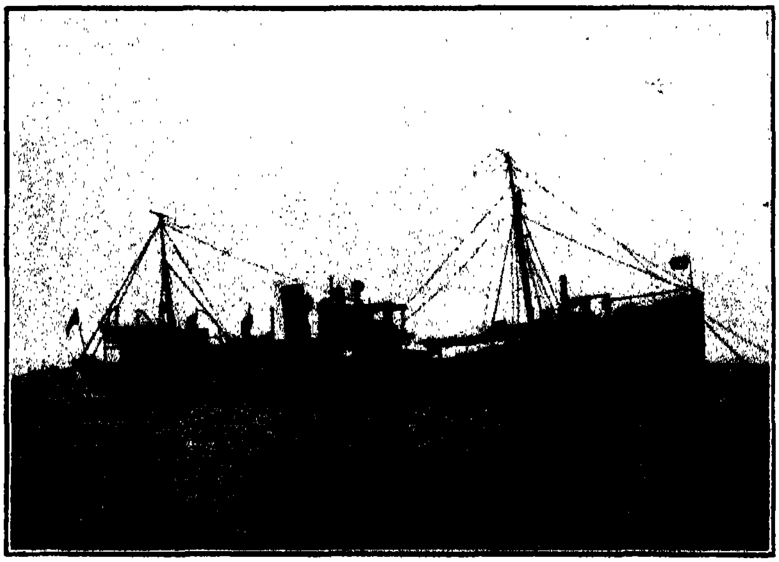
Meet the Sciences. By W. M. Malisoff. Pp. vi + 196. (Baltimore, Md.: The Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1932.) 15*s.* 6*d.* net.

CLASSIFYING the sciences has been a pleasant and harmless game for the philosopher ever since the time of Plato. The complex growth of our knowledge has, however, of late discouraged amateurs of this kind of jig-saw puzzle. The trouble with it is that either the definition of any science is too wide and thus annexes foreign territory on its borders; or it is narrow and allows border provinces to be taken over by a neighbouring science. Yet, order of some kind is badly needed in the description of our present-day knowledge: this ungrateful task is courageously performed by the author of this book. The result of his efforts should be, for the scientific worker, a more tolerant understanding of his subject, and for science, a clearer conception of its humble aims and human value.

The John Murray Expedition

By PROF. J. STANLEY GARDINER, F.R.S.

THE late Sir John Murray, whose name will ever be associated with the *Challenger* Expedition, left for scientific purposes certain funds, which have been allowed to accumulate since his death. He desired that these funds should be used for a scientific expedition, a sequel to the *Challenger*, and such an expedition has now been arranged by his children, who are also his trustees. In seeking to carry out their father's intentions, they sought the advice of oceanographers of all countries as to its venue and objects. The responses were most gratifying, but many of the proposals were beyond the means at the disposal of the trustees, while others represented sections of research already in progress. All the replies were submitted to Drs. E. J. Allen and W. T. Calman, the writer acting on behalf of the trustees.



Barki, Alexandria

FIG. 1. The *Mabahiss*, for the John Murray Expedition of 1933-34.

Three practical proposals of areas for the research of an expedition emerged, namely, off the north-west coast of South America, the Indian Ocean and the Red Sea. It was felt that the last-named, an enclosed sea of more than 1,000 fathoms with a sill to the south of less than 100 fathoms, presented peculiar opportunities for intensive and continued research, but that this should be based on Ghardaga, the newly erected Egyptian marine station off the Gulf of Suez, rather than attacked by an isolated expedition. In all three seas, a knowledge of the bottom fauna and conditions was emphasised. In addition, the two oceans present problems of oceanic circulation of considerable complexity and of wide interest.

On consideration and inquiry, the difficulties of arranging a west American expedition proved insuperable, so that the referee's choice fell on the Indian Ocean, which had been suggested in several memoranda. One of the latter had been presented by Col. Seymour Sewell, director of the Indian Zoological Survey and formerly surgeon-naturalist on the *Investigator*, and he was invited to lead the expedition. The further plans have been worked out by a committee including representatives of the Admiralty, the British Museum, the Royal Society and the trustees of Sir John Murray, in co-operation with Col. Sewell. The Committee consists of Mr. J. C. Murray (chairman and treasurer), Vice-Admiral Sir H. P. Douglas, Capt. J. A. Edgell (hydrographer to the Admiralty), Dr. C. Tate Regan (British Museum), Prof. G. I. Taylor (Royal Society), Drs. E. J. Allen, W. T. Calman and Stanley Kemp and Prof. J. Stanley Gardiner (secretary).*

It would have gratified Sir John Murray to know that the Indian Ocean has been selected, since this ocean was deliberately omitted from the route of H.M.S. *Challenger*, the Indian Government having undertaken to carry out its exploration. The whole area proved too large for the elaborate and detailed research demanded to-day, so that the operations of the expedition are to be confined to the Arabian Sea, which is bounded to the south-east by the Maldive and Chagos ridge and to the south by the latitude which passes through the Seychelles. This area feeds the Red Sea to the north-west and the shallow Persian Gulf to the north, and its conditions to some degree are simplified by its continuous land-boundary to the north and east. Its deep sea life has never been collected save by the I.M.S. *Investigator* and then only by spasmodic observations and a few trawlings near the Indian coast. The *Valdivia* traversed the southern part of the area on her great cruise and the *Dana* crossed it on her way home. Lately, the Admiralty has taken serial water samples in and off the Gulf of Aden, and much attention has been paid for many years to the water movements by the Marine Division of the Meteorological Office. H.M.S. *Sealark* spent the season of 1905–6 amongst the islands and submerged banks to the south, visiting in turn the Chagos Archipelago, Mauritius and Seychelles, besides most of the smaller islands and banks. Her investigations were mainly concerned with coral formations, their growth and decay, the deep sea being studied mainly by soundings. Even to-day, except on certain steamer routes, the depths are little known. The greatest charted is 2,930 fathoms, and the average depth about 2,500 fathoms, with openings to the south of 2,000 fathoms between Seychelles and Chagos and perhaps between Chagos and Maldives. With this topography the question of water circulation from the surface to the bottom is naturally a subject of particular interest.

Great difficulty was experienced in obtaining a suitable ship of the trawler type for the expedition. Any vessel would have to be fitted with sonic sounding apparatus and few proved to be suitable. The best available vessel appeared to be the *Mabahiss*, which was built for scientific work by the Egyptian Government in 1929. The Committee placed its dilemma before Egypt, King Fuad being well known for his interest in oceanography, and at the same time pointing out the desirability of an Egyptian scientific expedition down the Red Sea. In reply the Egyptian Government most generously proffered the loan of the *Mabahiss* for the winter of 1933–34, the Committee to equip her with echo and other necessary scientific gear. This friendly action will be most deeply appreciated by science, the international appeal of which is thus recognised.

A further plan is to use the *Mabahiss* in 1934–35 for an Egyptian exploration of the Red Sea, the same scientific methods to be followed in both expeditions so that results will be strictly comparable. The Red Sea expedition will give a worthy start to the Ghardaga Marine Laboratory of the University of Cairo, which, possessing deep water and tropical conditions in its immediate vicinity and being of easy access from Europe, bids fair to become of great value to science.

According to the present plans, the *Mabahiss* will be commissioned at Alexandria and sail on September 1. She will be commanded by Capt. Mackenzie, formerly of the S.S. *Discovery*. Lieut.-Commdr. Farquharson, who has been seconded for the expedition, is to take charge of the echo sounding and other survey work. On his side, Col. Sewell will be accompanied by four biologists, two of whom will specialise on the physico-chemical side and two on the ecological. The officers and crew will be Egyptian, and there will be two research students from the University of Cairo. After anchoring for a night at Ghardaga, the *Mabahiss* will run a depth section down the Red Sea to the Gulf of Aden, where several weeks will be occupied in the investigations of its depths, bottom fauna and circulation. While a continuous graph of the surface temperature will be taken on board the *Mabahiss*, the surface water samples, collected not only by the *Mabahiss* but also by certain liners, will be sent to the University of Cairo for analyses. The deeper water layers, however, will be investigated on board the *Mabahiss* by rapid methods, and it is hoped that thereby estimations of hydrogen ion concentration, oxygen, phosphates, nitrogen compounds and silica or some of these may be so quickly available that they will be of help in the planning of future work.

So soon as the north-east monsoon has become established, the *Mabahiss* will proceed to run a series of parallel lines of soundings between India and Ceylon and the African coast, unless the results obtained determine otherwise. In any event, there will be a special cruise in the Gulf of Oman for comparison of its conditions with those of the Gulf of Aden, and this will be followed by a cruise down the Maldives, where Major Glennie of the Indian Survey will take a series of pendulum observations across the bank with the object of determining the depth of the foundations on which its coral reefs are built. On all cruises, stations will be established at intervals for serial temperature observations and to obtain water samples from the surface to the bottom. In certain regions, the deposits should be of particular interest, and they will be collected by sounding leads and conical dredges. It is suggested that the blue mud off South Arabia may well be of especial interest, as also the green sand (glauconite), which in places is found from 50 fathoms to more than 1,000 fathoms, and the conditions of formation of which are uncertain.

The investigation of the deep sea biology, to the understanding of which all observations, physical, chemical and topographical, will be applied, is to be especially concentrated in the Gulfs of Aden and Oman and off the East African coast. Otter and Agassiz trawls and dredges of standard sizes will be regularly employed down to 1,000 fathoms, as well as the Petersen grab. Quantitative estimations of the bottom may not be possible, but it is hoped that the fauna will be adequately represented in collections and to a considerable degree determined in depth zones. The 'mud line' at about 100 fathoms, so named by Sir John Murray, is of especial interest off the Arabian coast, which, in spite of a high water temperature and an apparently suitable topography, is almost devoid of coral reefs. In connexion therewith, the shallower coastal waters may be investigated, a motor launch being carried for this work. It is hoped also that transparency observations may be possible. Plankton as such is not an object of study since the collections obtained by the *Discovery*, *Dana* and other vessels are sufficient to tax the energies of systematic workers for twenty to fifty years. On the *Mabahiss* it will be collected mainly in connexion with the investigation of the water layers and movements, but mid-water nets will be employed for the examination of the fish and other swimming life.

It is impossible to lay down beforehand detailed plans of the John Murray expedition or indeed of any future marine exploratory expedition. The coming of echo sounding allowing all depths to be read as a ship proceeds on her course, the determination of temperature sections and the invention of rapid chemical methods to be applied on ship-board to water samples from the surface to the sea floor, have altered the planning of all future marine expeditions, the course of which will undoubtedly be determined by the results obtained.

The Contribution of Radiotelegraphy to Geophysics

On Thursday, April 27, the Kelvin lecture was delivered before the Institution of Electrical Engineers by Sir Frank Smith, who took as his subject, "The Travel of Wireless Waves". In the course of it, an interesting picture was presented of the position attained by modern research, both theoretical and experimental, on the mode of propagation of the electric waves employed in radio communication. Particular reference was made to the bearing of the results of this work on the general problems encountered in geophysics, and the manner in which modern research has provided the radio-geophysicist with an invaluable tool with which to probe into the higher reaches of the atmosphere.

The appropriateness of this lecture was expressed in the observation that Lord Kelvin first studied the oscillatory discharge of a condenser, and read a remarkable paper on it exactly eighty years ago. Kelvin also introduced a tool known as the 'image method', applicable to many problems of physics; and when this is applied to Hertz's dipole oscillator, the familiar pattern is obtained of the electric field due to an oscillating charge over a perfectly conducting plane. The energy radiated from such an oscillating dipole is in the form of electromagnetic waves, the properties of which are identical with light waves, due allowance being made for the difference in wave-length. The waves will travel in straight lines except for such deviation as will occur due to refraction or diffraction effects.

When Marconi successfully demonstrated the transmission of wireless signals around considerable portions of the earth's surface, much attention was directed to the problem of the manner in which the necessary deviation was produced. Fleming showed that refraction due to the variation of atmospheric density with altitude would produce a negligible effect, while similar conclusions were reached in a study of the diffraction effects, even making allowance for the conductivity of the earth and the resulting currents set up by the waves passing over it. Moreover, G. N. Watson found that in the case of diffraction the factor showing the dependence of the effect upon wave-length was of a different power from that obtained empirically and embodied in the well-known Austin-Cohen formula. The experimental investigations also produced later some remarkable results, such as the striking differences between day and night transmissions, and the unexpected potentialities of the shorter wave-lengths for long distance communication, in spite of their well-known rapid absorption by the earth.

The need for a 'deflecting' region in the upper atmosphere was recognised in a note published by Prof. A. E. Kennelly in March 1902. A similar suggestion was made by Heaviside in an article written in June of the same year and afterwards published in the "Encyclopædia Britannica". In 1912, W. H. Eccles directed attention to the possible influence of the ionisation of the upper atmosphere on the propagation of electromagnetic waves through it, and to the resulting differences in day and night transmission. A few years later, Watson overcame his previous difficulty in a calculation of the field intensity of a wave propagated in the space between the earth and a conducting shell concentric with it.

In such circumstances it is natural to find the radio worker turning to the geophysicist for some knowledge of the properties of the atmosphere. By the aid of direct measuring instruments, the geophysicist has learnt much of the detailed physics of the troposphere and lower portions of the stratosphere; but it is not until a height of about 50 km. is reached that much information of direct interest to the radiotelegraphist is supplied. At this height ozone is found as the result of the dissociation of oxygen by ultra-violet light, and this action is accompanied by ionisation, which naturally suffers a rapid reduction after sunset as a result of recombination. Further information on such ionisation in the higher regions of the atmosphere has been obtained from the study of aurora and also from investigations in terrestrial magnetism; and attention may be directed to the fact that Balfour Stewart in 1878 was the first to suggest that the daily changes in intensity of the earth's magnetic field are due to electric currents in the conducting portions of the upper atmosphere.

As a result of all this work, the radio investigator is informed that there exists, concentric with the earth, a spherical conducting layer, that the conductivity is due to electrons or ions, and that the conductivity varies with the direction so that electric waves penetrating the layer will be polarised. The probable ionising agents are ultra-violet light and charged or neutral particles projected from the sun, so that the layer is likely to be much more highly conducting on the side of the earth exposed to the sun than on the side in darkness. On this geophysicist's picture of the ionosphere no accurate scale of heights can be placed, nor can values of the ionisation density be assigned. It is merely known that the ozone is most dense at about 40 km., and that the electron streams produce aurora at heights of from 90 km. to above 500 km.

With all this information at his disposal, the radiotelegraphist has been able to obtain at least a qualitative explanation of many of the phenomena encountered in his experimental investigations of the results of emitting waves from a radio station. In the first place, it is clear that, so far as the waves sent along the ground are concerned, the distance to which they travel before their field intensity falls to some specified value increases as the wave-length is increased; and for this reason moderately long waves of wave-length 200 to 2,000 metres are employed for general broadcasting services. Next, the portion of the waves which are sent into the upper atmosphere will be refracted on entering the ionised portions and, upon reaching a height at which the density of ionisation is sufficiently great, the deviation will be such as to return the waves to the earth's surface. It has been found that on a wave-length of about 50 metres and using an antenna power of 5 kilowatts, these waves returning from the ionosphere reach the earth and affect a receiver at a minimum distance of the order of 2,500 miles. Since under the same conditions the ground wave will only be detectable at distances up to about 90 miles, there will be an annular space around the emitting station having inner and outer radii of 90 miles and 2,500 miles respectively in which no signals will be detectable. This is commonly known in radio engineering circles as the 'skip' effect and the larger radius above is termed the 'skipped distance'. As the wave-length is increased, this distance decreases steadily owing to the greater refraction effects taking place in the upper atmosphere; at the same time the range of the ground wave increases, and finally the two overlap for wave-lengths approximately in the shorter broadcasting band of 200 metres to 500 metres. Under these conditions, both ground and atmospheric waves reach the receiving station, and it is the interference effects resulting from these two sets of waves which cause the well-known phenomena of fading in broadcast reception, and of the variation of bearing in radio direction-finding.

In the later portion of his lecture, Sir Frank Smith described how the radio investigator has recently directed his attention to obtaining more conclusive proofs of the existence of the ionosphere and to the quantitative measurement of its properties; that is, to obtain information which the geophysicist has been unable to supply. Methods employed in other branches of physics have been adapted to radio communication for this purpose. One of these makes use of the interference effects obtained between the ground and atmospheric waves to determine the height of the ionosphere. The same objective has also been attained by using an echo method to measure the time taken by a pulse of electric waves to travel up to the ionised deflecting layer and return to earth. Owing to the very high velocity of the waves, this time interval is short—about one-thousandth of a second—and the cathode ray oscillograph has proved an invaluable tool in the determination of this quantity.

Working in this manner, the radiotelegraphist has conclusively proved the existence of the Kennelly-Heaviside layer in the ionosphere at an average height of about 100 km. The measurements showed that for most nights the height of this ionised layer gradually increases, a maximum value being reached about one hour before sunrise. Further investigation showed that on certain occasions and with wave-lengths less than 400 metres, the height of the deflecting layer suddenly changes from 100 km. to about 230 km. It then became evident that on such occasions the density of ionisation in the Kennelly-Heaviside layer is insufficient for the deflection of the shorter waves, which thus penetrated this layer, but are ultimately deflected by a second layer above the first, the existence of which had not previously been suspected. This upper layer has been named after Prof. E. V. Appleton, who, with the co-operation of the Radio Research Board, has played the leading part in Great Britain in the investigations just described.

Having fixed the heights of these two important regions of the atmosphere, it has next been found possible to determine the density of the ionisation in these regions by ascertaining the limiting wave-length or frequency of the waves which will just penetrate the layer. Experiments carried out in this manner have shown that the ionisation is at its maximum about noon and decreases steadily as sunset is approached. After sunset, a rapid fall in ionisation takes place until, at about two hours afterwards, its value is only about one-tenth of the maximum, and this then remains reasonably constant until shortly before sunrise. Two further facts which emerge from the work are that there is very little ionisation between the Kennelly-Heaviside and the Appleton layers, and that, for wave-lengths less than about 8 metres, the waves penetrate both layers and there is as yet no evidence of their return to earth from the upper atmosphere. As to the cause of the ionisation, some data obtained during the solar eclipse of August 31, 1932 appear to establish the fact that the principal ionising agent for the two layers is ultra-violet light. The possible bombardment of the earth by neutral particles is not yet wholly excluded, but undoubtedly the evidence so far is against it.

The review provided in this lecture shows very clearly that the modern radio research worker is obtaining detailed quantitative knowledge of certain portions of the atmosphere in a manner which was beyond the reach of the former geophysical methods of attack.

Hydrogenated Motor Lubricants

THE recent display of advertisements has directed public attention to a new oil, "Essolube", a product representing the much-discussed process of hydrogenation successfully applied to the refining of petroleum. This particular lubricating oil is the product of many years research, involving much expenditure and the laying down of large-scale plant. The entry of hydrogenation as an established commercial process in the oil industry is an event of first-class technical and economic importance, and in many respects it will be a surprise to most people that the first satisfactory synthetic product in this field is a lubricant, a class of material distinguished for its extreme variability and one of the most sensitive (in performance) of the whole range of petroleum distillates.

Broadly speaking, it is demanded that a high-quality lubricating oil should possess a good viscosity index, a low pour point, a wide range of stability, high flash point and low carbon value; these properties are claimed as entirely characteristic of the synthetic product. A good viscosity implies an oil which changes least in characteristics with temperature range, making for easy starting of an engine in cold weather, reducing wear of the moving parts and, at the same time, ensuring that under operating conditions an adequate oil film is preserved round the piston; these factors naturally affect the question of oil consumption. The essence of stability is the ability of the oil to preserve its fundamental characteristics in performance, and the lack of tendency to form sludge or to coagulate in any manner which might tend to choke the lubricating system. The low carbon value is sought for many reasons; chiefly to take care that, whatever carbon is formed, is of a soft and non-crystalline character, as hard carbon particles returned to the oil sump will inevitably act as an abrasive and do damage to the vital parts of the engine.

Production of modern lubricating oils is, quite apart from this new process, a highly specialised subject, concerning which much still remains to be, and is being, done in the matter of fundamental research. Possibilities of hydrogenation as applied to petroleum products have of course been long foreseen by technologists both in Great Britain and in America, but the advent of a marketable product at this juncture is certainly a most commendable departure.

An account of this enterprising action of the Anglo-American Oil Co., the concern responsible for the introduction of this new lubricating oil, appears in the *Times* of April 29. Concurrently with the appearance of this product, the same Company is responsible for introducing a new method of delivery of the oil to motor engines. Supplies will be fed directly to the engine from sealed glass bottles and the displacing of the familiar tin will be an advantage in many ways since, apart from guaranteed measure, the contents can be seen and, incidentally, the shape of the bottle is such that it can be easily inverted into the oil filler of the engine, thus obviating loss by spilling, especially where such fillers are placed in awkward positions.

It is of interest to note the Company's exhibition of hydrogenation at Charing Cross Underground Station, a place, incidentally, one now instinctively associates with modern commercial enterprise in educating the public to at least some visual knowledge of commodities in everyday use which, in a vast majority of cases, are taken very much for granted. So much has been heard of, and written about, hydrogenation in the last few years without, to the lay mind, as yet any tangible expression, that the coincidence of a new synthetic hydrocarbon and the display of technique and issues involved, will do much to awaken interest in the untiring service that science renders to the community to-day.

Lessons in Visualisation from the Royal Academy

By Dr. Vaughan Cornish

SCENERY is defined as the appearance of a place from the picturesque point of view, and so, without pausing to consider what constitutes picturesqueness, we may note at once that scenery is an appearance. The science of scenery is, therefore, a science of appearances, and consequently the question whether a landscape painting is true to the facts can only be answered if we know how the physical surroundings are pictured through the agency of the eye.

There are three very different modes of picturing landscape; by the camera, by the representational school of painting, and by the imaginative school. Leaving the discussion of the last category for another occasion, let us now compare the rendering of the facts of scenery by the camera and by the school of painting hitherto dominant at the Royal Academy.

Even within the limits of monochrome, to which the camera is usually restricted, a clear photograph of a well-lit landscape is radically different from the natural picture. Not only the eye of the artist but also that of the ordinary man is selective. The natural picture of the landscape is not the sum of those features which we can see when we examine bit by bit the whole field of outlook, but a *composition* formed of that which we notice spontaneously. It may even be that in scenes which stir the emotions deeply, the proportion that remains unnoticed, that is to say mentally invisible, is greatest.

Largely on account of this selective action of the eye, and not merely on account of the vagueness of the image near the edge of the retina, the skilful composition of the landscape painter is in some important respects nearer than the photograph to the facts of scenery. It may be suggested in passing that the customary preference of the landscape artist for painting largely from memory, is not only on account of the troublesome variation of light in the actual scene, but also because memory is selective, and its partialities help to obliterate the inessential from the mental picture.

As an example of truth to Nature (in the wider sense) as exemplified in the school of landscape painting usually dominant at the Royal Academy, I may cite "The Shores of Clyde" (340) by

Mr. Robert Houston. This is an entrancing picture of sea and sunshine, flowering gorse and sheep grazing, cottages of fisher folk by the shore (at the foot of the hill from which the scene is viewed), a rocky islet catching the light, and in the distance a range of mountain peaks suffused with the tranquil, atmospheric blue. A few clouds are floating high, and from above the field of sight, the sun streams down, casting a broad lane of light upon the rippling summer sea. It all seems so natural, and exactly as we recall the scenery of Scotland in its happiest mood. The descriptive title of the picture does not tie us to a particular view-point, and this is fortunate for the average man, who is apt to feel that some deception has been practised when he finds the natural features arranged otherwise than as he is accustomed to see them from a specified view-point. In this connexion it is well that scientific people should recall the fact that mathematicians exercise a license somewhat similar to that of the artist in the generalisation of geophysical facts. The tidal bore in the River Severn, for example, does not always conform to the type of wave to which mathematicians restrict the name, although the mathematical conception was largely based upon this local example.

The water-colour "Gate Crag, Grange, Westmoreland" (1039) by Mr. Harold Gresley, has a definitely locative title, but as I am not acquainted with the particular spot the question of composition does not obtrude, and I simply welcome a delightful rendering of the charm of the English Lakeland. A single-arched bridge spans a rapid stream beside which stand the simple, whitewashed houses that Wordsworth loved. The foliage of pleasant round-topped trees diversifies the vale, and in the background the steep fell-side stands in shadow, with white clouds half uncovered, half hidden by the rugged mountain crest.

The sympathetic rendering of such scenes is always welcome, but it must be confessed that our painters have been less alert than the cameramen in availing themselves of modern facilities of transport for extending their range of subjects. Such pictures as that by Mr. Norman Wilkinson ("Territorials", 385) are as welcome as they are rare. The view, from an aeroplane, is of companion aeroplanes, backed by the piled domes of massive cumulus revealed in all their grandeur from a more advantageous point of sight than the ground provides.

When the man of science goes to the Royal Academy to learn what he can from the artist, it is well that he should not confine his attention to landscape, for pictures of interiors also convey lessons in visualisation. That of "The Library, Eaton Hall" (235), by Mr. Frederick W. Elwell shows a long gallery with the amplitude of dimension relatively to the human figure which is an outstanding advantage of the great country mansion. The perspective of such an interior satisfies certain faculties of the eye for which the natural landscape does not provide appropriate exercise. Moreover, the appointments of the room illustrate the fact that a well-furnished interior can provide more satisfaction for the eye in respect to diversities of texture than any natural scene. Here we have, skilfully painted, the glaze of pottery and porcelain, the glint of metal, the lustrous reflexion and transmission of glass vessels, and the polish of fine wood-work. Rich and varied as are these textures, it is the vase of flowers which brings the ultimate refinement of texture to the furnished interior.

Obituary

SIR JIVANJI MODI, C.I.E.

WE regret to record the death at Bombay of Sir Jivanji Jamshedji Modi, the widely-known and highly esteemed Orientalist, on March 28, aged seventy-two years. He was born on October 26, 1854, the son of the head priest of the Parsee Fire Temple at Colaba on the island of Bombay, and was educated at Elphinstone School and College. The studies to which he gave special attention, and in which he won a world-wide recognition as the foremost authority, were the origins, literature and teaching of Zoroastrianism, as well as the history of the Parsee community. For many years he was the secretary of the Parsee Panchayat in Bombay. He was one of the most active members of the Bombay Branch of the Royal Asiatic Society, which recognised his services to Oriental studies by the award of the Campbell medal in 1918. He was prominent in promoting the Oriental Research Institute at Poonah in memory of his friend, Sir Ramkrishna Bhandarkar, and did much work in connexion with the Cama Oriental Institute.

Sir Jivanji Modi's very considerable published contributions to scholarship for the most part appeared in the form of monographs, which were afterwards collected and republished in volumes such as his "Asiatic Papers", in four parts, "Anthropological Papers", also in four parts, "Memorial Papers", "Dante Papers", etc. He also wrote a history of the Parsees and published a number of translations from the Pahlavi.

His learning was widely recognised in both India and Europe; although it may be said without detraction from his scholarship that his commanding position in the world of Oriental studies was in some degree enhanced by his singleness of purpose and charm of character, which won the admiration and affectionate respect of all with whom he came into contact. He had long been a fellow of the University of Bombay, which conferred on him the degree of LL.D. in 1930. The Government of India made him an honorary correspondent of the Archæological Society in 1914 and conferred on him the title of Shams-ul-ulama. He was made a C.I.E. in 1917 and knighted in 1930. He was one of the few honorary members of the Royal Asiatic Society, an Officier d'Académie and Chevalier of the Legion of Honour.

WE regret to announce the following deaths :

Commdr. W. M. Carey, R.N.(retd.), captain of the R.R.S. *Discovery II*, which has just completed its second cruise, during which the Antarctic Continent was circumnavigated, on May 2, aged forty-six years.

Prof. R. E. Jeffs, associate professor of botany in the University of Oklahoma, known for his work on plant physiology, on February 11, aged fifty-three years.

Prof. Jules Piccard, formerly professor of chemistry at the University of Basle, aged ninety-three years.

Sir Arthur Whitelegge, K.C.B., chief inspector of factories from 1896 until 1917, author of "A Manual of Hygiene and Public Health", on April 25, aged eighty years.

Mr. E. B. Williamson, formerly assistant curator at the Carnegie Museum, and since 1930 research associate in the Museum of Zoology of the University of Michigan, who was an authority on dragon-flies, on February 28, aged fifty-five years.

News and Views

Portraits at the Royal Academy

IN addition to the pictures at the Royal Academy mentioned by Dr. Vaughan Cornish in his article elsewhere in this issue, scientific workers will be interested in the following portraits: Prof. S. Alexander, honorary professor of philosophy in the University of Manchester, charcoal, by Francis Dodd (1212); Sir Richard Glazebrook, formerly director of the National Physical Laboratory, by Edward I. Halliday (390); Dr. George Francis Hill, director and principal librarian of the British Museum, bronze medallion by Frank Bowcher (1650); Prof. J. G. Lawn, mining engineer, director of and consulting engineer in England to the Johannesburg Consolidated Investment Co., Ltd., bronze bust by Maggie Mitchell (1736); Dr. Eleanor Lodge, formerly principal of Westfield College, London, by Gerald F. Kelly (91); Sir Murdoch Macdonald, president of the Institution of Civil Engineers, bronze bust by Gladys Barron (1725); Lord Melchett, director of Imperial Chemical Industries, Ltd., by Glyn Philpot (274); Dr. Alexander Scott, director of scientific research at the British Museum, head by Sir W. Reynolds-Stephens (1638); the late Sir William Smith, founder of the Royal Institute of Public Health, bust by Charles L. Hartwell (1602); and Sir J. J. Thomson, master of Trinity College, Cambridge, chalk, by W. T. Monnington (1180). Among the other exhibits are a tempera of the foundations of the new Geological Museum, South Kensington, by Laurence Wheatley (881); while the architectural drawings and models section includes the library of the same Museum, by John H. Markham (1405), proposed additions to the Ashmolean Museum, Oxford, by Stanley Hall, and Easton and Robertson (1400), the completion of wings to Gower Street of University College, London, by Richardson and Gill (1512); and an etching and dry point of Battersea Power Station, by H. R. Myerscough-Walker (1257).

New Gorilla House at the Zoological Gardens

THE new Gorilla House at the Gardens of the Zoological Society of London was opened on Friday, April 28. Sir Peter Chalmers Mitchell, in a short but admirable speech, traced the origin and the merits of the new house, which are many; indeed, there is no other like it in Europe. Having regard to the rarity of gorillas in captivity, and their frailty, it was felt that an entirely new method of housing them should be devised. The general plan of the house was conceived by Sir Peter, but its elaboration was entrusted to Mr. B. Lubetkin, of Messrs. Tecton Ltd., architects. Briefly, it forms a large, circular chamber divided into two equal portions, a winter and a summer house. In the winter, the public have access in the half set aside for summer, and they are shut off from the animals by a glass screen to eliminate the danger of infection from influenza by the public. The air in this enclosure is filtered, warmed, and moistened, before passing into the chamber, which is free from draughts. Here we saw the two gorillas which the Society has now had since last August in a particularly frolicsome mood, due no doubt to the ample proportions of their apartment. In the summer the semicircular wall and roof of iron which forms the winter "Hall of Audience", is caused, by machinery, to pass behind the winter house, leaving it fully exposed to the sun and air, and enclosed only by strong bars. The glass partition is also withdrawn, leaving a great circular space wherein the animals may furnish their visitors, now standing outside, with opportunities for studying the habits and movements, of these, the largest and most powerful of all the great apes.

New Autogiro

A NEW model of Senor de la Cierva's autogiro, incorporating a radical alteration in the method of control, was demonstrated by the inventor at the London Airport, Hanworth, on April 27. The autogiro derives its lift from a number of blades rotating in a horizontal plane, instead of fixed wings as in a normal aeroplane. Thus there is relative motion between the blades and the air, with consequent lift, even when the machine has little or no forward speed. The autogiro can therefore fly with little speed relative to the earth, and can land and take off almost vertically. Hitherto, the orientation of the machine when airborne has been governed by the orthodox aeroplane aileron, elevator and rudder for lateral, horizontal, and directional control respectively. This new model, Type C.30, replaces all of these controls by altering the direction of the resultant lift of the rotors by tilting their supporting pillar. A lever attached to this column is pulled back to make the nose rise, forward to drop, sideways to turn and bank correctly at the same time. Thus the pilot's task in the air is considerably simplified, although apparently at the expense of a certain amount of rapidity in manœuvrability. Another advantage of this new control is that its effectiveness is a function of the speed of the rotating blades, and not of the forward speed of the machine as in the normal aircraft. It is therefore equally effective at low flying speeds, a particularly important point in landing, taking off, and flying near the ground generally. The absence of the usual control surfaces and their supporting parts should give a considerable saving in both weight and head resistance, and should simplify construction. A fixed tail plane and a vertical fin are still retained for stability, and a tail wheel controlled by an orthodox rudder bar is used for turning on the ground.

Royal Institution

THE annual meeting of the members of the Royal Institution was held on May 1, the president, Lord Eustace Percy, being in the chair. The annual report of the Visitors for the year ended December 31, 1932, testified to a year of considerable activity. The membership had been well maintained. The privilege of free attendance at the afternoon lectures by *bona fide* students in London had been much appreciated and used. The report on the progress of the researches in the Davy Faraday Laboratory gave a good indication of the considerable extent of the research organisation which is at work under the direction of Sir William Bragg. Some sixteen or eighteen workers are engaged, the majority on problems related to the X-ray determination of structure. Mention was made of Dr. J. M. Robertson's determination of the structure of anthracene, of Dr. A. Müller's work on the long-chain compounds, and of the growth in accuracy and capacity of the large experimental X-ray plant in the hands of Dr. Müller and Mr. R. S. Clay. The capacity of the apparatus is calculated to be about 50 kw.; as yet it has worked well up to 10 kw. The treasurer's report and accounts showed a very satisfactory position, in spite of the heavy demand on the financial resources of the Institution caused by the recent reconstruction. After a total expenditure in connexion with the rebuilding of more than £100,000, a diminution in the invested funds of the Royal Institution of about £2,000 is shown. This gratifying result is a consequence of many generous donations to the Building and Research Endowment Fund raised by the Institution in the past three years. The donations and other receipts to this fund have been sufficient to defray almost the entire cost of the rebuilding, and to go a considerable way towards completion of the programme of permanent endowment of research which the Managers of the Institution have as one of their principal objects. The following officers for 1933–34 were elected: *President*, the Right Hon. Lord Eustace Percy; *Treasurer*, Sir Robert Robertson; *Secretary*, Major Charles E. S. Phillips.

Portrait of Sir William Bragg, K.B.E., O.M., F.R.S.

AFTER the formal business of the annual meeting of the members of the Royal Institution, a portrait of Sir William Bragg, painted by Mr. William Nicholson, was presented to the Institution, on behalf of a group of subscribers, by the honorary secretary, Major Charles E. S. Phillips, who expressed the gratification of the donors at having secured the help of so distinguished an artist. Mr. Nicholson had given them, he said, not only a good portrait of Sir William, but also a very fine painting. Major Phillips went on to pay a tribute of admiration for the work of Sir William Bragg and to speak of the affection in which he is held by the members and all others with whom he comes into contact in his work. The portrait was accepted by the president, who thanked Major Phillips for having taken the initiative in regard to its painting and presentation, resulting in a valuable acquisition to the permanent treasures of the Institution. Sir William Bragg spoke briefly of his own pleasure at the expressions of goodwill with which the presentation had been made, and said that the success of the work of the Royal Institution was largely due to the friendship and devotion of its members, who had always responded freely to any request for services or appeal for help.

Centenary of Hancock's Steam Omnibus

To commemorate the centenary of the inauguration of the first power-driven omnibus in London, a joint meeting of the Newcomen Society and the Omnibus Society was held at the Institute of Marine Engineers on April 27 at which papers were read by Mr. C. E. Lee and Mr. C. F. D. Marshall. Mr. Lee said that the three principal pioneers of the steam omnibus were Goldsworthy Gurney (1793–1875), Walter Hancock (1799–1852) and John Scott Russell (1808–1882), of whom Hancock was the most successful. A watchmaker by trade, Hancock patented a very ingenious type of boiler and then built two steam carriages, the second of which, called the *Infant*, in February, 1831, began running between Stratford and London. Two years later, the London and Paddington Steam-Carriage Co. was formed and for this Hancock built the omnibus *Enterprise* with accommodation for fourteen passengers. This vehicle began running between Moorgate and Paddington on April 22, 1833, and was the first mechanically propelled vehicle specially designed for omnibus work ever to be placed in service. The route covered was about ten miles and the distance was performed in about fifty minutes. The service was worked for 16 days only, under the superintendence of Hancock, and was then withdrawn owing to differences between him and the Company. Three years later, after other experimental work, Hancock had other steam vehicles at work and in the course of twenty weeks these ran 4,200 miles and carried 12,761 passengers. Both the papers contained much information on the construction of these and other early steam omnibuses and it cannot be doubted that if the inventions had been fostered, instead of hindered, by legislation, the steam vehicle would have been brought to a high degree of perfection at an early date.

Observational and Theoretical Astronomy

ON April 28, Prof. H. H. Plaskett delivered his inaugural lecture as Savilian professor of astronomy at Oxford. Recalling the fact that the year of the foundation of the professorship was also that of the publication of Kepler's three laws of planetary motion, and directing attention to the injunction of Sir Henry Savile that the holder of his professorship should occupy himself with "observation by day and night", he remarked that three hundred years ago the observational method in astronomy might be said to have reached its zenith. Since then, the constantly increasing importance of the theoretical method has been abundantly shown; as, for example, in the discovery of Neptune by calculation and in the present conclusions as to the physical conditions in the interior of stars. Nevertheless, the achievements of theoretical astronomy still rest in part on an observational basis. This is shown by consideration of the means by which knowledge of the spatial distribution of the stars has been gained by the work of Herschel and Shapley, and of that of their physical constitution by the work of Lockyer, Franklin and Hertzsprung. It would be fair to say, looking forward to the next three or four hundred years, that it will be allowed that, so far, observation and theory have gone along hand in hand. In a more distant future it may not be so. At present, theory has played its part in the refinement of observation, but some of the results of theory must for ever be removed from observational control. But just as the explorer of the earth's surface suggests to the geographer plans for further fruitful exploration, so the astronomer going to Nature with a definite theory may succeed in getting an answer. Finally, there can be no doubt that a great university should have an observatory as part of its equipment; but it must be recognised that the part of astronomy under these conditions necessarily has its limitations.

Lachish

EXCAVATIONS at Tell Duweir in Palestine, where the Wellcome Historical Museum Expedition has been at work under Mr. J. L. Starkey, have now closed for the season. The particular interest of this excavation lies in the possibility that the site may be the city of Lachish which was captured by Joshua after a stout resistance. So far, nothing has been found to contradict this tentative identification, while some of the evidence from this season's work tends to confirm it. Lachish was captured by Sennacherib in 701 B.C.—this siege is represented on bas-reliefs from Nineveh now in the British Museum—and by Nebuchadnezzar in 586 B.C. Tell Duweir, which is situated about twenty-five miles south-west of Jerusalem at a height of 900 ft. above sea-level, dominating the Philistine country, is a mound of some forty acres in extent, tapering to eighteen acres at the summit. The stone walls identified with the city of Rehoboam show the breaches made by Sennacherib's army and traces of the conflagration by which they were made to collapse under Nebuchadnezzar. Under the stone walls of Rehoboam's city were found the red brick walls which are identified with the city of Joshua's day. A further piece of evidence pointing in the direction of the identification is the find of a metal helmet crest which corresponds with the crests on the peculiarly shaped helmets of some of Sennacherib's soldiers shown on the British Museum bas-reliefs. Part of a royal palace on the summit of the mound was uncovered, and a number of graves at the base belonging to all ages were examined and yielded a large number of skulls in excellent preservation. Objects from Tell Duweir will be on exhibition at the Wellcome Historical Museum, Euston Road, London, N.W.1, on their early arrival in England.

National Research Council of Canada

THE National Research Council of Canada has issued a statement covering its sixteen years work which indicates a close parallel between the activities of this Council and those of the Department of Scientific and Industrial Research in Great Britain. In addition to the direction of a wide range of investigations in a National Research Laboratories system, the development of a national library of science, and the publication of a *Canadian Journal of Research*, the Council has developed co-operation in research throughout Canada, instituted a policy of grants to individual research workers, and assisted in the training of scientific personnel by the award of scholarships to selected students and graduates. Its efforts have raised the whole standard of research in Canada and in addition the National Research Council has already proved its value in the day-to-day problems of government and to various State departments. During the sixteen years of its existence, the Council has paid a total of 527,951,000 dollars in research scholarships and 131,801,292 dollars in grants for research. More than half of the total expenditure has been incurred on the building and organisation of the National Research Laboratories, which were formally opened on August 10, 1932, and have already made notable contributions to scientific knowledge and industrial development.

FROM a summarised account of these activities occupying nearly fifty pages, it is only possible to select a few points as illustrations. Important contributions to the asbestos industry have been rendered by investigations on asbestos cements and the standardisation of testing and methods. Studies of the resistance of concrete structures, the development of a highly resistant cement, of the treatment and disposal of sulphur dioxide fumes from smelter stacks, waste gas and bitumen utilisation, on the prevention of rust on wheat and other cereals and on weed killing, have already proved of great economic advantage to the whole country as well as to the particular industries. There is scarcely one of Canada's wide range of interests—agriculture, mineral industries, transport, fisheries, building, fruit growing, coal, leather, wool—to which the Laboratories are not offering direct service. Highly important work has already been carried out on rubber and extensive facilities have been provided for standardising and testing all classes of materials.

Metropolitan-Vickers Research and Testing Departments

A BOOKLET which has just been issued, describing the Research and Testing Departments of the Metropolitan-Vickers Electrical Co., Ltd., Trafford Park, Manchester, shows what an important part industrial research plays in the advancement of science. The somewhat fragile and makeshift construction of the equipment of many science laboratories is often due to an excessive use of glass, rubber and similar materials. Modern engineering principles, materials and manufacturing methods have led to great improvements. The original research work carried out by the scientific staff of the Company has led to many important developments. In particular, the discovery of the Apiezon series of low-pressure oils and distillates has led to highly important advances in vacuum technique. Valves, X-ray tubes, etc., can now be taken to pieces for repair and adjustment and then re-assembled for use. They can also be made of materials like metal and porcelain and so have not the disadvantages of permanently sealed glass apparatus. The physics and engineering staff have done excellent pioneering work in many branches of research. Their vacuum furnaces, their arrangement of apparatus to apply testing pressures of a million volts continuously and their testing methods for impulse pressures as high as one and a half million volts are scientific triumphs. In developing apparatus for measuring noise they have broken new ground. The principle on which the apparatus works is that of aural comparison of the complex noise under observation with a pure reference tone of fixed frequency but adjustable amplitude. By listening simultaneously to the two sounds and adjusting the loudness of the reference tone until it sounds as loud as the noise under observation, the loudness of the complex noise can be expressed, by an experienced observer, in terms of that of the simple reference tone.

Railway Electrification Experience

COL. CORTEZ LEIGH, electrical engineer to the London, Midland and Scottish Railway Co., read a paper to the Institution of Electrical Engineers on April 6, which attracted a large audience. He described the experience gained by working the electrical railway between Manchester and Altrincham, a distance of about nine miles, since it was opened in May 1931. It appears that notwithstanding the competition of a recently inaugurated express bus service, the increase in the passenger traffic was 35 per cent. This is attributed to the greatly accelerated service made possible by electrification and to the increased comfort of travelling. Another reason is the great success of the 1,500-volt mercury arc rectifiers, the first used in Great Britain for railway work, for converting the alternating current supply into direct current for the railway motors. It looks as if these devices would come into general use, seeing that the 1,500 volt D.C. system was standardised by the Pringle Committee in 1927. This will make it easy to merge into a general scheme of main line electrification later. In the discussion, H. W. H. Richards, electrical engineer of the London and North Eastern Railway, compared the straight electric drive adopted on this line with the Diesel electric drive which has been much advocated lately. He calculated that the straight electric drive takes forty per cent less power. Prof. W. Cramp referred to the wear of the overhead conductors which are in contact with the pantograph collectors. It has been found that the wear of the conductors when the wires are oiled is about six times less than when there is no oil. Sir Josiah Stamp said that the results obtained on this line have more than fulfilled expectations.

The Palæontographical Society

THE eighty-sixth annual meeting of the Palæontographical Society was held in the rooms of the Geological Society, Burlington House, on Friday, April 28, Dr. F. L. Kitchin, vice-president, in the chair. The annual report recorded the publication of vol. 84 of the monographs, containing instalments of the Corallian Lamellibranchs, Gault Ammonites, and Cambrian Trilobites. It is anticipated that vols. 85 and 86 will be issued during the present year, thus bringing the publications more nearly up to date. Dr. F. A. Bather, Mr. Robert S. Herries, and Sir A. Smith Woodward, were re-elected president, treasurer, and secretary respectively; and Mr. F. H. Edmunds, Dr. W. D. Lang, Prof. S. H. Reynolds, and Prof. W. W. Watts were elected new members of council.

Science Forum

HOWEVER on financial grounds the apparently unending stream of new scientific organisations and publications may be deplored, one cannot honestly withhold sympathy when these are founded with the object of promoting international co-operation in the general advancement and practical development of science in all its phases. The first issue of the *Science Forum*, the quarterly journal of the International Faculty of Sciences, is therefore of interest as an indication of the manner in which it is proposed to achieve these objects. The articles include discussions on the relation of science and religion by Dr. Ernst Almquist, and on changes in moral ideas likely to result from the study of psychology in relation to ethics by Dr. R. Money-Kyrle. W. H. Wakinshaw's "Consufiatia" provides a useful elucidation (with an unconvincing solution) of the world's economic problems, and an interesting note on the gladiolus scab and its prevention comes from

R. H. Jeffers. The articles are written in a semi-popular strain with, however, a slight tendency to emphasise the sensational which should be firmly repressed if the publication is to carry weight among scientific workers or thinking laymen.

Auguste Rateau, 1863–1930

THE late Prof. Auguste Camille Edmond Rateau, whose death was recorded in NATURE of February 8, 1930, held a chair at the School of Mines at St. Étienne for about ten years. When, in 1897, he resigned this position, he was succeeded by M. Emile Jouquet, who in the *Annales des Mines* for September 1932 gives a full account of the researches and inventions of his distinguished predecessor. The son of an architect, Rateau at an early age gave signs of mathematical talent and when he completed his two years' study at the Ecole Polytechnique, he passed out at the head of his class. He was twenty-five years of age when in 1888 he was made a professor in the School at St. Étienne, where previously, as M. Jouquet says, Burdin was a professor and Fourneyron, "the Watt of the hydraulic turbine", was a student. Rateau's work was in direct line with theirs and from it came the Rateau mine ventilators, centrifugal pumps and steam turbines. The impulse steam turbine of Rateau was applied to a French torpedo boat in 1904 and Rateau turbines, as developed by the Ateliers et Chantiers de Bretagne, Nantes, have recently been fitted in the fastest flotilla leaders in the world. A prominent member of many societies, Rateau was elected a member of the Paris Academy of Sciences in 1919. A monument to him was unveiled on January 17, 1931, in the grounds of the works of the Société Rateau at La Courneuve (Seine).

Expedition to South-Eastern Honduras

THE Smithsonian Institution, Washington, D.C., announces the dispatch of an expedition of archæological exploration to the Chorotegan area of south-eastern Honduras. The members of the expedition are Messrs. Alan Paine, W. D. Strong and Norman Haskell. The Chorotegan area is one of the least known in the whole of America and no trustworthy maps of it exist. The object of the expedition is to locate and determine the character of ancient ruined-city sites, to collect specimens of bird and animal life, and to get into touch with the practically unknown Payas and Sumu Indians, whose language, thought to be linguistically on the border line between North and South America, may throw light on the language of the ancient Maya. The specific problem to be investigated is the possibility that the culture of this area may have been a southward extension of the Mayan 'New Empire' of Yucatan, three hundred miles to the north. From time to time, natives and chicle hunters have reported the existence of ancient ruined stone cities in this area, and it is believed that it was from here that the Maya obtained the precious metals and the turquoise, of which they made such extensive and elaborate use in their decorative art.

Air Survey Methods

THE increasing use of aerial photography for mapping makes the publication of a simple handbook on the subject very welcome. This has been written by Lieut. J. S. A. Salt under the title of "A Simple Method of Surveying from Air Photographs" and published as No. 8 of the Professional Papers of the Air Survey Committee (London: H.M. Stationery Office, 4*s*.). The book aims at explaining the methods required in the production of medium-scale maps based on a limited ground control and involving the use of comparatively simple apparatus. The demands made on pilot and navigator are explained and there is a full discussion of the relation between ground control and plotting and the problems of the cartographer in general. The work is clearly written and amply illustrated with diagrams and plates. It should prove a useful guide and textbook.

Announcements

DR. C. TATE REGAN, director of the British Museum (Natural History), has been elected a foreign member of the Royal Danish Academy.

MR. CHARLES AUGUSTUS CARLOW was elected president of the Mining Institute of Scotland at the annual general meeting held on April 26.

THE Rubber Industry Bill was introduced in the House of Lords by Lord Irwin, president of the Board of Education, on May 2, and read a first time. The Bill provides for contributions by the rubber manufacturers in the United Kingdom to the Research Association of British Rubber Manufacturers, and for the collection and application of such contributions.

THE Challenger Society for the Promotion of the Study of Oceanography is offering a sum of money, not exceeding £25, for the assistance of a suitable student (or students) carrying out research at any of the marine laboratories. Application should be made to the Hon. Secretary, Mr. J. R. Norman, British Museum (Natural History), South Kensington, S.W.7.

FROM the interest of the Sir George Beilby Memorial Fund, awards are made to British investigators in science to mark appreciation of records of distinguished original work, preference being given to investigations relating to the special interests of Sir George Beilby, including problems connected with fuel economy, chemical engineering and metallurgy. Two awards of £250 each were made in 1930, and two awards of £105 each in 1932. The administrators will meet in June, and will be glad to have their attention directed to outstanding work of the nature indicated. Correspondence should be addressed to the Convener, Sir George Beilby Memorial Fund, The Institute of Chemistry, 30, Russell Square, London, W.C.1, not later than June 1.

THE Rockefeller Medical Fellowships for the academic year 1933–34 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than

June 1. These fellowships are awarded to graduates who have had some training in research work in the primary sciences of medicine, or in clinical medicine or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. In special circumstances, the fellowships may be tenable at centres of research not in the United States. A fellowship held in the United States will have the value of not less than £350 a year for a single fellow, with extra allowance for a married fellow. Full particulars are obtainable from the Secretary, Medical Research Council, 38 Old Queen Street, Westminster, S.W.1.

Additional lists of articles chargeable with duty under Part I of the Safeguarding of Industries Act, 1921, have been issued by the Board of Trade, and will take effect as from May 12. These lists refer to articles under the following headings:—Optical Instruments; Scientific Glassware; Scientific Instruments; Synthetic Organic and other Fine Chemicals. Copies of the lists may be obtained from His Majesty's Stationery Office, price 2*d*. net.

National Baby Week in Great Britain will be held on July 1–7, and among the topics for special consideration this year is preparation for parenthood. A conference on maternity and child welfare, organised by the National Association for the Prevention of Infant Mortality, will take place on July 5–7, at the Friends' House, Euston Road, London, N.W.1. Free displays of propaganda films in London are also being arranged. Further information can be obtained from the Secretary, National Baby Week Council, 117, Piccadilly, London, W.1.

As from July next, *Science Progress*, the well-known quarterly review of scientific thought, work and affairs, will be published by Messrs. Edward Arnold and Co., London (7*s*. 6*d*. net per copy). The principal features of the review are being retained by the new publishers, though typographical improvements are being made. Each issue will contain at least one article by a leading man of science describing work with which he has been identified; in the July number this feature will be contributed by the Astronomer Royal, Dr. H. Spencer Jones.

John Evelyn's "Fumifugium or the Inconvenience of the Aer and Smoake of London Dissipated", dedicated to Charles II and published in 1661, has been reprinted by the National Smoke Abatement Society, with an introduction by Rose Macaulay (National Smoke Abatement Society, 23, King Street, Manchester; 1933. Paper, 6*d*. net; cloth, 1*s*. 6*d*. net). Modern work on atmospheric pollution shows that conditions in London have changed, and that it is the domestic fire rather than the factory which is now fouling the air. Nevertheless, Evelyn's pungent invective and constructive proposals make interesting and entertaining reading. It will be recalled that the pamphlet was also reissued as an Old Ashmolean Reprint three years ago (Oxford: Dr. R. T. Gunther, Folly Bridge, 1930. 2*s*. 6*d*.) and was reviewed at length in Nature of March 8, 1930, p. 368.

In a notice of the second edition of Pohl's "Einführung in die Mechanik und Akustik" in Nature of April 22, p. 568, the hope was expressed that an English translation would be made available. Messrs. Blackie and Son, Ltd., have reminded us that they have already published an English translation of this edition of Pohl's book. It was reviewed in Nature of March 4, p. 320.

A biography entitled "Charles Parsons—His Life and Work" by Rollo Appleyard, will be published on May 11 by Messrs. Constable and Co., Ltd. The book contains the life-story of the Hon. Sir Charles Parsons, whose achievement in developing the modern turbine and dynamo, and in applying them to the propulsion of ships and for power stations, marks him as one of the leading engineers of his time.

Prof. Julian S. Huxley has accepted the invitation of Messrs. Thornton Butterworth Ltd. to become science editor of the "Home University Library", in succession to the late Sir J. Arthur Thomson. The "Library", founded in 1911, and added to each year, now consists of more than 160 volumes covering the chief subjects in history and geography, literature and art, science and social science, philosophy and religion. Prof. Huxley joins the Right Hon. H. A. L. Fisher and Prof. Gilbert Murray on the editorial side.

Applications are invited for the following appointments, on or before the dates mentioned:—A technical assistant to the Secretary of the Institution of Structural Engineers—The Secretary, 10, Upper Belgrave Street, S.W.1 (May 10). A head of the School of Architecture and Building in the Technical College and Central School of Arts and Crafts, Plymouth—The Secretary for Education (May 12). A student assistant in agricultural economics in the Department of Agriculture and Horticulture at the University of Bristol—The Agricultural Officer, 22, Berkeley Square, Bristol, 8 (May 12). A principal of the Kenton Lodge Training College for Women, Newcastle-upon-Tyne—The Director of Education, Education Office, Northumberland Road, Newcastle-upon-Tyne (May 15). An assistant pathologist to the Infirmary and demonstrator of pathology in the University of Sheffield—The Registrar (May 17). A full-time engineering workshop instructor in the Municipal Technical School, The Gamble Institute, St. Helens—The Secretary for Education, Education Office, St. Helens (May 22). An assistant engineer to the Great Yarmouth Water Works Co.—The Secretary, 84, York Road, Great Yarmouth (May 22). Five district veterinary officers in the Public Health Department of the Cheshire County Council—The Clerk to the County Council, County Offices, Chester (May 27). Robert Blair fellows in applied science and technology, tenable overseas—The Education Officer (T.3), County Hall, London, S.E.1 (June 1).

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Egyptian Neolithic Barley

WHEN, where and with what species man first began the cultivation of grain are questions intimately bound up with the development of our civilisation. Fresh light has been thrown on these questions by specimens of grain which were found a few years ago in the course of explorations carried out in Egypt by Miss G. Caton-Thompson and Miss E. W. Gardner, who have given preliminary accounts of their work in two papers[1]. The archæological and geological evidence given in these papers shows that this grain was grown between 5,000 and 6,000 B.C. by a people in a Neolithic state of culture, living on the shores of a lake, which still exists, though now much smaller than in Neolithic times.

In the course of the work, more than a hundred small straw-lined pits were found which had served as granaries. Most were empty but several contained agricultural implements, and eight, varying quantities of grain, which, in five cases, was entirely or mainly wheat, but, in three, to a large extent barley.

The number of varieties of barley in cultivation is very great, amounting to several hundreds; these varieties or, at any rate, groups of them, are fairly well confined to different parts of the world. As my work during a good many years past has made me familiar with many of them, I thought it would be interesting to see how these ancient specimens compared with modern barleys; by the kindness of Miss Caton-Thompson, I have been able to do so.

Of the three specimens containing barley, one was found to be in a practically perfect state of preservation; some 800 corns were examined, with the following results:—

Wheat	20 per cent
Barley (6-rowed) ..	57 ,,
,, (2-rowed) ..	23 ,,

As I have no special knowledge of the varieties of wheat, I did not examine this further but confined my attention to the barley, the characters of which were compared with those of modern barleys grown not only in Egypt but also in other Eastern countries, namely, Tunis, Syria, Danubian countries, Persia and India. The result of this comparison was to show that this prehistoric barley was to all intents and purposes identical with that in cultivation in Egypt at the present time and clearly distinguishable from the barleys now grown in the other countries mentioned.

These facts give rise naturally to the thought that, since no appreciable improvement can be seen to have taken place in it during the last seven thousand years, a very long time must have been needed for this barley to have developed from the wild state to the degree of perfection which this specimen shows; in other words, the origin of agriculture must have been long before 5,000 B.C.

The other evidence collected by Miss Caton-Thompson and Miss Gardner permits of a few more conclusions being drawn as to the part which cereals and their cultivation played in the lives of these people.

From the size of the pits and on the assumption that the contents of each pit were the produce of one area and the property of one family of, say, 5–10 persons, it is evident that these people were not essentially an agricultural folk, for the proportion of grain in their food supply was less than in modern England, whereas in truly agricultural populations like those of India or China, it is very much higher. Its cultivation must have made small demands upon their time, which must have been spent mainly in fowling and fishing. They were, therefore, a people in the interesting intermediate stage between hunting and agriculture, and it is significant that we find them on the borders of a lake, for the presence of water must have been a most important, if not the most important, factor in bringing about the difficult transition between hunting and agriculture. A hunter is essentially a wanderer; an agriculturist essentially a settler. Even if the brilliant idea of growing wild grass instead of merely gathering it did occur to a hunter, there would be little inducement for him to do so, for the game might move away at any time and he could never be sure that he would be able to return at the right time to reap it nor could he give it any attention while growing. But if, as in this case, he were already more or less anchored to a spot where it was easy for him to obtain his food supply by the methods of hunting and fishing, with which he was already familiar, he would be very favourably placed for supplementing it by practising the newer method of tilling the ground.

Chemical Detection of Artificial Transmutation of Elements

IF detection of elements originating from artificial transmutation can be attained by chemical methods, not only will this mean a desirable checking of physical observations, but also new results may thereby be obtained. For physical means of discerning the transmutation of elements—whether by observing scintillations or by electrical methods—presuppose that the atoms which originate are expelled with a certain minimum energy; processes which take place with lesser energy remain at present unknown to us, even although they are perhaps quantitatively more important than the already ascertained cases of artificial disintegration of atoms.

First may be discussed the question whether the hitherto known modes of artificial disintegration of atoms offer any prospect of giving sufficiently large amounts of matter for a chemical test of the new products. Here we will confine ourselves to hydrogen, helium and neon, as so far we have worked only on these elements, and because the methods of their analysis are amongst the most sensitive of all. Several years ago we ascertained[1] that under the most favourable conditions the practical detection-limit for helium is within the order of magnitude of 10^{-10} c.c. (that is, about 10^{10} atoms), and that one can recognise with certainty 10^{-9} c.c. helium (about 10^{11} atoms). As hydrogen and neon possess lower excitation potentials than helium, the presence of these two gases as small admixtures can be spectroscopically observed; according to an early statement of Collie and Ramsay[2], 10^{-3} per cent of hydrogen in helium can still be recognised. Since by our method the slight amount of helium, which forms from the α-rays used for the artificial disintegration of atoms, can be isolated and spectroscopically examined[3], there would therefore be a possibility of finding in this the content of hydrogen originating from atomic disintegration, if its quantity stood in no more unfavourable ratio than that of 1 : 100,000 to the helium. Now, in many cases of artificial atomic disintegration, the yield of hydrogen is at least of this order; and it seemed therefore not altogether unpromising to attempt spectroscopically to detect hydrogen originating in the disintegration of atoms by α-rays.

Our numerous experiments in this direction have been unsuccessful, for the reason that it was not possible for us with small amounts of helium to verify Collie and Ramsay's statement. We have not succeeded in preparing in glass vessels helium which was with certainty free of hydrogen; as Collie and Ramsay say nothing about hindering hydrogen liberation from the glass, it seems to us that the hydrogen lines observed by them may have been due to some contamination rather than that they should be attributed to the intentionally added amount.

Much more favourable are the circumstances for testing neon in helium. Here the influence of glass walls, and the danger of deception through the leakage of neon from the atmosphere, can be precluded. We have found that down to 2×10^{-5} per cent neon in helium can certainly be detected, and probably even less. This gave a possibility of proving whether, by bombarding a substance with α-rays, neon originates in larger amounts than 1 atom to 100,000 α-particles. Hitherto we have had only negative results (the limits of which are nevertheless so low that they are not uninteresting); we were able to ascertain that by bombarding oxygen with α-rays, such neon as may be formed falls short of that proportion; herein, as pointed out above, is included any rayless production of neon. Other experiments in bombarding the fluorides of potassium and sodium with α-rays also gave no definite positive effects.

At present the best prospects for spectroscopic identification are given by helium originating in consequence of a bombardment of lithium, boron, etc., with protons, according to Cockcroft and Walton's process[4]. The number of from 10^{10} to 10^{11} helium atoms, which is necessary for the application of our method, must form themselves in reasonable time if a somewhat stronger stream of protons is applied and the main amount of helium developed is intercepted; if we can assume that helium rays of even shorter range than those already known are present, then the prospects of results are still more favourable. We are now occupied, in conjunction with physical laboratories, in chemically isolating, and spectroscopically testing, the helium originating after bombardment with protons; also the effect of electrons of high speed on the formation of helium is being investigated.

We have also made experiments to find out whether helium appears after bombardment with β-rays or neutrons. In the case of both these rays, the abovementioned extremely small amounts of helium would be detectable, but as yet the use of moderately strong radio-active preparations (about 50 mgm. of radium) has given no suggestion of the formation of helium[5]. The proof of helium originating under α-bombardment is naturally less sensitive by many orders of magnitude; the quantity of newly produced helium would need to amount to several per cent of that originating from the α-rays, and such a yield of an artificial transmutation would surpass all that has hitherto been observed in this sphere. Nevertheless it seemed to us worth while using our micro-method of quantitative helium measurement[6] to ascertain the amount of helium which developed from various substances after bombardment with the unfiltered rays of thorium-B and thorium-C, namely, with a mixture of α-, β-, and γ-rays and recoil atoms.

While with water, carbon, potassium, tin and mercury the amount of helium found corresponded, within a ten per cent limit of error, to the number of α-particles which had been shot into the substance, in the case of carbon-hydrogen compounds, such as paraffin, palmitic acid and diphenyl, we have found surpluses up to a hundred per cent. We hope to interpret this surprising phenomenon after further experiments; but as the completion of our work may be hindered, we therefore make this preliminary statement.

Orientations of Molecules in the *p*-Benzoquinone Crystal

THE crystal structure of *p*-benzoquin recently been studied by W. A. Caspari[1] methods. The crystal belongs to the system and is assigned by Caspari to t group C^5_{2h}; there are two molecules in t ntra of cell, the molecules possessing a centre of sym an s His X-ray measurements are not sufficient to de der mine uniquely the orientations of the molecules the unit cell. However, by combining his X-ray data with certain considerations concerning the crystal habit and the dimensions of the molecules, he concludes that the molecular planes are parallel to (201) and that the lines joining the two oxygen atoms of the molecule lie in the (010) plane. This orientation of the molecules secures a large concentration of the oxygen atoms in the $(20\bar{1})$ plane, which concentration, according to Caspari, will account for the exceptional development in the crystal of so peculiar a face as $(20\bar{1})$.

It seems to us that the molecular planes in the crystal are orientated differently. A study of its magne-crystallic properties shows that the $(20\bar{1})$ plane is indeed the mean plane of the molecules. Denoting by χ_1 and χ_2 the principal gram molecular susceptibilities of the crystal in the (010) plane, and by χ_3 the susceptibility along the *b* axis, we find that

$$\left.\begin{array}{l}\chi_1 = -27\cdot 1\\ \chi_2 = -64\cdot 5\\ \chi_3 = -25\cdot 4\end{array}\right\} \times 10^{-6} \text{ c.g.s. e.m.u.}$$

The χ_2 axis, which is plainly an axis of approximate magnetic symmetry, is inclined at 20·2° to (001) and at 87·0° to ($20\bar{1}$).

We may compare the above principal susceptibilities of the benzoquinone *crystal* with those for the *molecule* of the substance—deduced from the known constants for the benzene molecule. We then find that χ_1 and χ_3 are about the same as the susceptibility of the molecule for directions in its plane, while χ_2 is nearly equal to the susceptibility of the molecule along the normal to its plane. We may therefore conclude that the molecular planes in the crystal are perpendicular to the χ_2 axis, and are thus almost coincident with the ($20\bar{1}$) plane.

The orientation proposed by us is also supported by the optical properties of the crystal. Since the optical polarisability of the benzene ring for vibrations perpendicular to its plane is known to be considerably smaller than for vibrations in the plane, the refractive index of the crystal for vibrations perpendicular to ($20\bar{1}$) should be a minimum and be much less than the other two principal refractive indices. This is indeed so, since the crystal exhibits a strong negative birefringence, and the acute bisectrix is almost perpendicular to ($20\bar{1}$).[2]

Detection of Traces of Carbon Monoxide in Air

A PARAGRAPH among the "Research Items" in ATURE of March 25, page 441, states that Dr. kermann has made comparative tests of two s of estimating carbon monoxide gas in air: dous chloride method and the hæmoglobin The latter method consisted in exposing globin to the gas to be examined; then a reducing agent (ammonium sulphide) to moglobin and examining it with an ordinary roscope for the presence of the two absorption nds of carbon monoxide hæmoglobin.

With palladous chloride it was possible to detect 0·015 per cent of carbon monoxide as against 0·13 per cent with the hæmoglobin method.

I should like to point out that there is a better hæmoglobin method than that used by Dr. Ackermann, which depends on the wave-lengths of the bands of oxyhæmoglobin being different from those of carbon monoxide hæmoglobin. Thus the α band has a difference of wave-length of about 60 angstrom units for ox, sheep or human blood. This change in wave-length can under suitable conditions be estimated with an accuracy of 1 angstrom unit by means of the reversion spectroscope.

Dudley, Edmed and Frederick have recently used this instrument[1] for investigating the production of carbon monoxide gas by various paints. Some of the air analyses showed values as low as 0·004 per cent carbon monoxide. Substituting this value for that obtained by the hæmoglobin method by Dr. Ackermann, the comparison with the palladous chloride method would now be:

Hæmoglobin method (with reversion spectroscope) ..	0·004
Palladous chloride method (Dr. Ackermann)	0·015

This reverses the conclusion reached by Dr. Ackermann, for the hæmoglobin method appears to be the more delicate.

Radioactivity of Samarium and the Formation of Hibernium Halos

IN their interesting communication to NATURE for March 25, p. 434, G. Hevesy and M. Pahl have referred to Joly's work on the so-called hibernium halos. The agreement between their determination of the range of the α-ray radiation of samarium and Joly's[1] value is very striking. He found that the air equivalent of the radius of a hibernium halo was 1·15 cm., which may be compared with their figure for the range of the samarium α-ray of 1·1 cm. In his final estimate of the range of the hibernium α-ray Joly gave 1·5 cm. This figure was arrived at from the fact that in a normal positive uranium halo the boundary of the halo does not coincide exactly with the full range of the α-ray, due to the decreasing ionising power of the ray very near the end of its path. It must be remembered, however, that all the hibernium halos observed were reversed halos, and, as is shown later, it is probable that some non-radioactive reversal and intensification effect is necessary to render them visible, if they are samarium halos. Under these conditions it is possible that the radius of the halo would give practically the full range, which would thus agree nearly exactly with the samarium α-ray range.

When we consider whether a samarium nucleus of the size observed in the hibernium halo would furnish sufficient α-ray radiation to produce a halo since Archæan times, we encounter certain discrepancies. The radius of a hibernium halo is 5×10^{-4} cm., with a central nucleus of about 3×10^{-5} cm. radius. If this nucleus were a pure samarium sphere, its mass would be $8\cdot 7 \times 10^{-13}$ gm. Using Hevesy and Pahl's value for the number of α-rays per gram of samarium, that is, 75 α-rays per gram per second, this sphere would emit $2\cdot 0 \times 10^{-3}$ α-rays per year. Taking a rough figure for the age of the Archæan of 10^9 years, and allowing for the total volume of the complete halo sphere, we arrive at a total number of α-particles per cubic centimetre of halo sphere of $4\cdot 0 \times 10^{15}$.

Unfortunately, no quantitative measurements on the effect of α-rays on the very opaque Ytterby mica are available. Joly and Rutherford's[2] experiments on Ballyellen mica show that it requires about 2×10^{14} α-particles per cubic centimetre to produce an amount of staining corresponding to a weak positive halo in this material. The amount of α-ray radiation required to produce a reversed halo must be very much greater than this, as is shown by Jedrzejowski's[2] work on the production of reversal by α-ray radiation of a Siberian mica. Thus if we are to assume that hibernium halos are due to samarium, we must either conclude that Ytterby mica is specially sensitive to α-ray radiation, or that some reversal and intensification of the halos has been produced by either thermal or chemical effects in the course of their long history. I am inclined to favour the latter alternative, since I have observed a similar intensification of positive halos when heated to a temperature not sufficient to obliterate the halo by the blackening of the surrounding mica[4]. Joly, also, has observed the reversal of immature uranium halos in Ytterby mica. The fact that hibernium halos are so rare, even in Ytterby mica, is perhaps explicable on the view that the conditions for the reversal and intensification of the halos are only very occasionally satisfied.

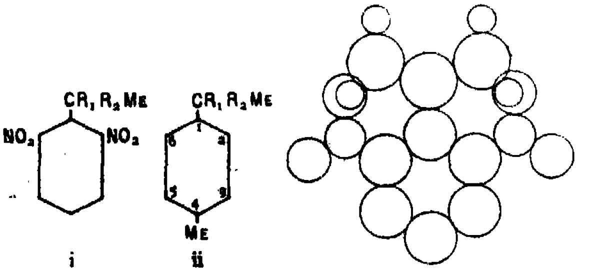
Volumes of Alkyl Groups and their Orienting Powers

IN some of their applications, the current generalised theories of benzene substitution discard steric factors too lightly. For the purpose of *a priori* consideration, it can be assumed that the effective reagent in a substitution does not occupy a *smaller* volume than the group which is eventually installed in place of hydrogen.

A drawing to scale[1] is reproduced (Fig. 1) of the compound (i): the groups R_1 and R_2 are omitted and the two positions which could be taken by the methyl group in the plane of the benzene ring are indicated.



Scale drawing of (i)

FIG. 1.

It is seen that some degree of interlocking of groups occurs. Various applications of this are at present under investigation; for example, that during nitration of (ii), attack by HNO_3 molecules at the 2- and 6- positions might be impeded by a real screening effect from the $-CR_1R_2Alk$ radical. To a less extent the same might apply to halogenation. Thus the absolute number of reagent molecules colliding with these positions may be less than those colliding at 3- and 5-, and/or some of the reagent molecules may succeed in penetrating to the 2:6-carbon atoms only after preliminary collision. In the last case, their kinetic energies being reduced, the threshold energy of activation necessary for substitution is likely to be attained less frequently than among the more direct collisions occurring at positions 3- and 5.

Expressed differently: if velocities of substitution can be represented by $k = \alpha\, e^{-E/RT}$, then in compounds of the type now under discussion the two pairs of vicinal positions available for substitution will be abnormal in not having identical α terms (contrast Bradfield and Jones's results[2]). Such abnormality must be expected with all alkyl substituents larger than methyl.

The net consequence will be a depression of substitution ortho to the radical, $-CR_1R_2Alk$ in favour of other positions where substitution will be able to occur by default. Thus orientation in discord with electronic theories (requiring substitution more at positions of greater electron availability) should be expected from *a priori* reasoning alone.

Experiments on the nitration and halogenation of *p*-cymene and some of its derivatives have justified this conclusion. The results with the hydrocarbon itself are tabulated:

2-Substitution in 1-methyl-4-isopropylbenzene.

268 G *p*-cymene subjected to:—	Total wt. of crude material isolated	Unchanged *p*-cymene recovered	Theoret. yield for mono substn.	Pure 2 substd. cymene obtd.	Per cent in crude product.	Per cent yield on cymene taken
Nitration .	290	—	358	252	87	70
Chlorination .	318	1	338	200	63	59
Bromination .	376	19	396	214	57	54

The numbers in the last column give minimum estimates of the yields of 2-derivatives obtained in these experiments. The amount of actual 2-substitution of *p*-cymene in each case is certainly greater than is indicated by these results. Thus methyl appears to possess a greater ortho directive influence than isopropyl. On pure electronic theories the reverse should be the case.

Nuclear Moment of Arsenic

THE hyperfine structure of two-electron spectra of heavy elements with configurations involving an *s* and one other type electron have been under investigation for some time in this laboratory. The As IV spectrum, classified by K. R. Rao[1], is of this type, and is particularly suited for the detection of hyperfine structure and the determination of the moment of the nucleus. About a year ago, the As IV lines λ3216, 3190, 3109 ($4s5s\,{}^3S_1 - 4s5p\,{}^3P^\circ_{012}$), excited by a condensed electrodeless discharge, were examined with a multiple prism spectrograph and found to have comparatively large hyperfine structures. The patterns, although not completely resolved, showed that the *I* value of arsenic was small and probably equal to 1½. The recent acquisition by this Department of an excellent 21 ft. concave grating, ruled by Prof. Gale of Chicago, has made possible the completion of this investigation. The results definitely show that the nuclear moment of arsenic is 1½ × $h/2\pi$.

The line λ3216 ($^3S_1 - {}^3P^\circ_0$) is well resolved in the fifth order, and shows three components decreasing in intensity from the red to the violet and separated by the intervals 0·907 and 0·544 cm.$^{-1}$. Since the $^3P^\circ_0$ term is not split by the nuclear interaction, the triple line-structure corresponds directly to the hyperfine structure of the $^3S_1$ term. This triplet structure shows that $I \geqslant 1$, and the interval ratio definitely fixes I as $1\frac{1}{2}$. Theoretically, the interval ratio for a term with $J = 1$ is $(I + 1)/I$. The observed ratio, obtained by averaging twenty measurements from two plates, is $0{\cdot}907/0{\cdot}544 = 1{\cdot}67$. It is evident that the only value of I that satisfies this ratio is $1\frac{1}{2}$. The intensities are consistent with this value of I and they, with the intervals, show that the hyperfine levels of $^3S_1$ are normal.

The lines λ3190 ($^3S_1 - {}^3P^\circ_1$) and λ3109 ($^3S_1 - {}^3P^\circ_2$), although not completely resolved in the fifth order, both show four distinct components. These structures were interpreted by Fisher and Goudsmit's method for incompletely resolved patterns[2]. In both cases the positions and the intensities[3] of the fine structure components were consistent with the predictions based on the known separations of the $^3S_1$ term, obtained from λ3216, and on the deduced value $1\frac{1}{2}$ for I, which was used to determine the interval ratios of the $^3P^\circ_1$ and $^3P^\circ_2$ terms.

The interval factor of $^3S_1$ is $A(^3S_1) = 0{\cdot}363$ cm.$^{-1}$. The interval factors of the other two terms are $A\,(^3P^\circ_1) = 0{\cdot}18$ cm.$^{-1}$, and $A\,(^3P^\circ_2) = 0{\cdot}15$ cm.$^{-1}$. The last two were determined by the graphical method and are not so accurate as the first. The approximate equality of $A\,(^3P^\circ_1)$ and $A\,(^3P^\circ_2)$ shows that the coupling in the $4s5p$ configuration approximates to the (LS) type[4]. This is consistent with the multiplet separations of the $4s5p\ {}^{3,1}P$ terms: although the interval ratio 3·2/1 for the $^3P^\circ_{012}$ separations[1] differs appreciably from the ratio 2/1, the g-factors calculated by Houston's method[5] depart only slightly from those for (LS) coupling.

The nuclear moment deduced from the hyperfine structures of these As IV lines is in agreement with the value deduced by Tolansky[6] from the hyperfine structure of As II. His publication appeared during the course of this investigation.

The $4s5p$ configuration of As IV and the $4p5s$ configuration of As II illustrate nicely the influence of binding on coupling. The coupling energy between the s and p electrons is expected to be about the same for both configurations. The (ls) interaction of the p electron in the $4p5s$ configuration is expected to be from two to three times that of the p electron in the $4s5p$ configuration. This follows from an application of the Landé doublet formula when the screening effect of the two $4s$ electrons[7] and the variation in n^* are taken into consideration. Due to this increase in the (ls) interaction relative to the interaction energy between the two electrons, the coupling in the $4p5s$ configuration should depart more from (LS) type than the coupling in the $4s5p$ configuration. This is consistent with observation: the coupling in $4s5p$, as pointed out, approaches (LS) type, whereas the coupling in $4p5s$ differs considerably from (LS) and tends toward (jj), as shown by the application of Houston's theory[5] to the multiplet separations and of Goudsmit's theory[4] to the hyperfine separations of As II.

In this research, hyperfine structure was also observed in several unclassified spark lines. These structures are being investigated.

The authors wish to thank Prof. E. F. Burton, director of the Laboratory, who co-operated and made possible the completion of the investigation by procuring the new grating.

Photochemical Reaction of Hydrogen and Chlorine

PROF. BAKER and I have talked over the matter dealt with in his letter to NATURE published in the issue of January 7, p. 27, namely, the influence of traces of water vapour on the above reaction. We agree that no further discussion of the point at issue would be useful unless combined with a simultaneous first-hand and detailed examination of the experimental method used. This is impossible, as the apparatus in question has been dismantled. We therefore, for the time being at all events, hold to our respective and divergent views on the subject.

About three years ago Dr. J. B. Bateman, working in this Laboratory with dispersed monochromatic light, obtained results which indicated that the quantum efficiency for this reaction fell off in the ultra-violet, and became practically zero somewhere below 3000 A. Recent experiments carried out by Mr. H. C. Craggs under rather different conditions have shown that the results were due to the presence of a plate of glass, instead of quartz, at the exit side of the thermopile mounting in which the telescope slit of the monochromator is incorporated. This in turn was due to an unfortunate misunderstanding for which we can take no responsibility. In view of the extraordinary nature of the original conclusion, Dr. Bateman's work was not published in full, pending further confirmation. The results have, however, been quoted on two occasions—at a Faraday Society discussion in April 1931 and in a contribution to a Chemical Society discussion held in December 1931. On that account I think that a formal withdrawal is necessary.

Sacred Sandstone of the Mayas

ALL archæologists are familiar with the work done on the remarkable Maya ruins at Chichen Itzá, in Yucatan, by Mr. Earl Morris and his associates, on behalf of the Carnegie Institution of Washington (see NATURE, 128, 692, Oct. 24, 1931). In the course of uncovering the large building now known as the Temple of the Warriors, Mr. Morris found an older temple underneath it, which he was able to explore by means of suitable tunnels. It was in the basement of this older building that he found the beautiful turquoise plaque, now carefully restored so far as the materials permitted, and deposited in the National Museum of Mexico. The centre of this plaque consists of a circular area which was filled with pieces of polished hæmatite, and beneath this, as Mr. Morris has fully explained in his recent book, is a disc of sandstone, of very ordinary quality, but not obtainable near Chichen Itzà.

The exact meaning of all this has remained uncertain. Mr. Morris found other discs of sandstone in the foundations of the later temple, and had inferred that they must have been held sacred, without suggesting any reason beyond their position and the fact that they were carefully protected from injury. While hearing Mr. Morris lecture on this subject, it occurred to me that in all probability the discs were connected with human sacrifices. The porous stone would become largely saturated with blood, and would thus afford a means of preserving the actual blood of the sacrificial victim in the foundations of the temple. The symbolism of the covering hæmatite would then be evident; it would present the appearance, when polished, of a pool of blood. Further confirmation appears to be afforded by the discovery, in an adjacent building, of another plaque and with it, covered with turquoise, a large knife or blade. This might have been the sacred instrument used in killing the victim. It is a question whether careful analysis would reveal any traces of blood now remaining in the sandstone discs, but it seems not impossible that this might be the case.

After consulting with Mr. Morris, I offer this note to direct attention to the matter, hoping that someone may be able to supply decisive evidence.

Recording Wireless Echoes at the Transmitting Station

RECORDS of wireless echoes by the group-retardation method of Breit and Tuve[1] show that the intensities and number of echoes diminish as the receiver is brought near the transmitter. The minimum distance from the transmitter at which we could detect echoes was 400 metres[2]. The nearest distance at which interference phenomena between direct and sky waves have ever been noticed seems to be 180 yards[3]. The difficulty experienced in recording echoes at short distances from the transmitter is commonly supposed to be due to the enormous strength of the direct ground signal as compared with the strength of the echoes. This is undoubtedly one reason; but there is another reason to which proper attention has not been paid by investigators in this field.

FIG. 1.

In the group-retardation method, the transmitting aerial is energised for very short periods, for example, 1/5000 sec., at brief intervals of say 1/200 sec. The wave packet sent out during the active period of the aerial returns to the earth, during its quiescent period. During this latter interval, the transmitting aerial acts like a receiving aerial and collects energy from the reflected wave from over a comparatively large area surrounding it. The receiver with its small aerial, when brought within the 'collecting area' of the more efficient transmitting aerial, naturally fails to gather sufficient energy from the reflected wave and is unable to record the echoes.

It occurred to us that the difficulty mentioned above could be obviated if the transmitting aerial itself were utilised as a receiving aerial during its quiescent period when it absorbed energy from the reflected wave. Acting on this idea, the input coil of the receiver was coupled to the tuning inductance of the aerial, when echoes were recorded without much difficulty. A photograph of the echoes thus obtained is reproduced in Fig. 1. This, we believe, is the first record of echoes returned at absolutely normal incidence from the ionised layer. The direct signal of course comes out very strongly, but it can be kept down by suitable design of the receiver, such as by using an automatic volume control.

A great advantage of using the same aerial for transmitting as well as for receiving is that it dispenses with the necessity of erecting two stations, one transmitting and another receiving at two different localities, and employing two observers. A single observer is able to control and attend to both the transmitting and the receiving sides.

[2] Mitra and Rakshit, *Phil. Mag.*, **15**, 20; 1933.
[3] Appleton and Naismith, *Proc. Roy. Soc.*, A, **137**, 36; 1932.

WE were much interested in a valuable paper by Mitra and Rakshit on "The Upper Ionized Atmosphere in Bengal"[1]. Their extension, to sub-tropical regions, of soundings of the ionosphere is very important. We are not concerned here to point out the bearing of the magneto-ionic theory on the results obtained by these authors, but the reading of the paper leads us to record one point arising from our experience of such work.

The receivers customarily used in pulse-reception at this Station are of the frequency-conversion type, with a band-width of 10 kc./sec., and with a diode as second detector. The ground distance between sender and receiver is only 120 metres, and the receiver was designed with such time-constants that the heavy overloading produced by the ground-pulse did not appear to lengthen the duration of the corresponding output-pulse as seen on the cathode ray oscillograph. This arrangement gives very satisfactory echo-patterns, and meets all our immediate requirements.

We were recently disconcerted to find, however, that the receiver as a whole was rendered relatively insensitive, for periods of many milliseconds, by the incidence of the strong ground-pulse, so that the electric forces, particularly in the earlier members of the echo pattern, were in fact higher than would have been inferred from the screen amplitudes and the steady state gain. Work towards removal of this defect is in progress, and substantial improvement has already been attained.

We think it desirable even at this interim stage to direct attention to the possible existence of this defect as a contributory cause in the reduction of echo amplitude with ground distance reported by Mitra and Rakshit in their paper. It is clearly desirable that this instrumental point should be cleared up in each individual case before a geophysical interpretation of echo amplitudes is looked for.

Action of Quaternary Ammonium Salts on Nerve

EXPERIMENTS similar to those of Fromherz with curare on medullated nerve, referred to by Prof. A. V. Hill in his article on "The Physical Nature of the Nerve Impulse",[1] in NATURE of April 8, have been made with pure quaternary ammonium salts prepared by Dr. H. R. Ing. These have a curare-like action, preventing transmission of excitation from nerve to muscle, but not affecting muscle or medullated nerve directly in the concentration required for paralysis.

A frog's nerve, taken from a gastrocnemius-sciatic preparation which had been 'curarised' in Ringer's solution containing 2 millimols per litre of tetramethyl ammonium iodide or 1 millimol per litre of octyl trimethyl ammonium iodide, was asphyxiated until excitability had disappeared and then for a further hour. When oxygen was readmitted the nerve showed only a transient recovery of action current and this vanished in about half an hour. If a concentration of 2 millimols per litre of octyl trimethyl ammonium iodide or 1 millimol per litre of strychnine methiodide was employed, there was no transient recovery of action current on admission of oxygen. An increased dose of the two drugs first named, or the use of a similar compound of greater molecular weight, abolishes even the temporary return of the action current in oxygen after asphyxiation. A control nerve-muscle preparation left soaking in oxygenated Ringer's solution containing the quaternary ammonium salt was still 'curarised' at the end of the experiment, but when the nerve was cut off and tested the action current showed no diminution. Also, control nerves soaked in Ringer's solution without poisoning and then asphyxiated in the way described showed only a 15–20 per cent decline in action current.

Experiments made in September at the Marine Biological Laboratory, Plymouth, showed that the action current is abolished in the non-medullated nerves of *Maia squinado* by soaking for about a minute in sea water containing less than 1 millimol per litre of quaternary ammonium salt. As with veratrin, the salt can penetrate the non-medullated nerve without asphyxiation.

Further Light on the Schneider Mediumship

LORD CHARLES HOPE is correct in stating (NATURE, April 15, p. 549) that the 'suspect' detected in trickery at Dr. Osty's experiments was 'allowed' to attend every séance at my laboratory, but this was because Rudi Schneider refused point blank to sit without her.

It had been arranged to hold a series of sittings during the summer of 1931, but negotiations broke down because we refused to allow the 'confederate' (a close friend of Rudi's) to accompany him. When we found that Rudi would not visit the Laboratory without his friend, we consented to have her, but—after Dr. Osty's experiences—special precautions were taken to keep her under close observation during the séances.

Although Dr. Osty now admits that he detected Rudi's friend producing the 'phenomena' herself, his report contains no mention of this, and the fact that she was present at any experiment is not recorded in the account prepared for the public.

Stress has been laid on the fact that our cameras caught Mr. Schneider evading control, but so long ago as 1924 Professors Meyer and Przibram of Vienna detected Rudi producing 'telekinetic' movements of objects by means of a freed arm. That he *can* free an arm from the usual tactual control (and without the controllers being aware of the fact) has now been proved by our photographic evidence.

Mr. Schneider has promised to visit us during the coming autumn, when we hope finally to settle the question as to whether he can externalise some 'force' capable of displacing objects at a distance, or of affecting infra-red rays. We want 'Olga' (his trance personality) again to hand round flowers and cigarettes: to play the zither: to place a paper basket over a sitter's head: to give us another 'farewell signature'—all of which 'supernormal' diversions we witnessed at previous experiments.

Invar

IL n'est pas douteux que les recherches de M. Honda soient fondamentales, et aient apporté de sérieux progrès à nos connaissances sur les alliages de fer avec le nickel, le cobalt et le chrome. Mais je voudrais rectifier une petite erreur dans son exposé, paru dans le numéro de NATURE du 22 avril, 1933, p. 587. M. Honda dit, en effet, qu'on n'a pas pu réaliser un invar ayant une dilatation inférieure à $1{\cdot}2 \times 10^{-6}$. Or, les fils employés en géodésie, et qui ont une très faible dilatation, passant même quelquefois au-dessous de zéro, sont, depuis plus de vingt ans, de fabrication courante. Pour expliquer la faible dilatabilité de l'invar, on s'est fondé sur l'existence réversible de fer α et de fer γ. Des publications importantes sur cette question ont été faites, notamment par F. Osmond, Louis Dumas et Pierre Chevenard. J'y ai fait moi-même plusieurs fois allusion.

Research Items

Patwin and Maidu Cult Origins. A further investigation of the Patwin and Maidu tribes of California was undertaken by Mr. E. M. Loeb in 1931 with the object of adding to information previously obtained relating to the secret society organisation of northern California as it existed prior to 1870 (*Univ. California Pub. American Archæol. and Ethnol.*, 33, No. 2). The main cults of north-central California are local or autogenous units; but the specific traits entering into the cults usually are more widespread than the cults themselves, and therefore have come to north-central California by diffusion, when they have not arisen by a process of disintegration and amalgamation. Tribal initiation was the oldest cult, and its elements (the bullroarer, the tribal mark, the death and resurrection ceremony, and the representation of spirits or ghosts) probably were brought in by the American Indians on their entrance to the New World. Some of these were adopted by later cults; others lost, as the bullroarer among the Patwin-Maidu. 'Ghosts' may be split into three sub-traits—clowns, running spirits, and representatives of the dead. Of these, running spirits alone are indigenous to north-central California, while clowns originated in the south-west or in Mexico. Human representation of the dead occurs in Lower California, and on the Colorado. It is possible that the annual mourning ceremony was located in Mexico. The use of the scratching stick and sucking tube points to the origin of the initiation ceremony at one point in the world. They occur in both North and South America as well as in the Old World. While the kuksu cult has affinities with the south, the hesi cult comes from the north, bringing with it private ownership of dances and dance dress, and probably bear doctors, bear dances and bear propitiation. The kernel of the hesi cult may lie in first-fruit, and especially acorn, rites.

Pleistocene Dating of Gafsa Hills, Tunisia. M. R. Vaufrey has now published (*Rév. Géog. Phys.*, 5, fasc. 3) the communication presented to the Prehistoric Congress in London in August last, in which he brought forward evidence derived from the discovery of palæolithic implements *in situ* making it possible to fix, within certain limits, the date of the formation of the hills in the oasis of Gafsa, Tunisia. The low hills of the oasis, following the general conformation of southern Tunisia, run from north-east to south-west. It had been noted previously that the alluvial deposits, forming a conglomerate, of which the hills are composed, are tilted, the lamination being exposed by erosion on the north side. A considerable number of stone implements have been found on one of the hills, "la colline du signal", by previous investigators, notably Schweinfurth (1907) and de Morgan (1910), the former classifying the earlier implements elaborately according to the eolithic nomenclature of his day. One of the objects of M. Vaufrey's investigations, therefore, was to discover implements *in situ* with the view of establishing their exact relation to the tilting. Implements were found at three points in the tilted strata, the latest in type being an evolved Acheulean. On the other hand, in the horizontal strata of the alluvial deposits of later date which lie at the foot of the hills and have not been subjected to the folding to which the formation of the hills was due, he found a Mousterian implement, a typical Levallois flake. On this evidence he concludes that it is justifiable to fix the date of the formation of the hills at the interval between Acheulean and Mousterian, say, at the end of the Riss-Würm glaciation or at the very beginning of the last glaciation of the ice age. As he says in conclusion, this is the best example known of folding which can be attributed with certainty to the Pleistocene.

Internal Ear of Amphibia. C. Guareschi (*Mem. Roy. Accad. d'Italia, Classe Sci. Fis. Mat. Naturali*, vol. 3, pp. 147, 1932) records in detail the results of his experimental investigations on the internal ear of Amphibia, both Urodela and Anura. Into whatever region of an embryo of the same species and the same age the developing ear is transplanted, it will differentiate into an internal ear and the differentiation is independent of the relations with neighbouring organs and of the innervation. A part of the ear rudiment when transplanted is not capable of giving rise to the structures potentially contained in the other part. In the destruction which inevitably takes place in xenoplastic transplantations, after the absorption of the yolk, the otocyst presents a greater resistance than the eye, and its parts show a differential susceptibility resulting in the more rapid destruction of the sensitive area. Two otocysts may be made to fuse and the resultant is provided with all the structures contained potentially in the two rudiments. There exists an independence between the development of the cristæ and the maculæ.

Chromosomes of Amphibians and Fishes. In a series of five papers on the chromosomes of amphibians, Dr. Shigemori Iriki (*Sci. Rep. Tokyo Bunrika Daigaku*, vol. 1, p. 61) has added considerably to our knowledge of the cytology of this group, especially as regards the Japanese species. In two species of *Rana* he finds the diploid chromosome number to be 26, confirming his earlier count. In spermatogenesis he finds a V-shaped body which he interprets as a pair of X-chromosomes, and concludes that probably in all Anura the female is heterogametic for sex. He shows a spiral structure in the X-chromosomes of the male *Hyla arborea japonica*. Among Urodela, in *Diemyctylus pyrrhogaster*, $2n = 24$, while in *Megalobatrachus japonicus*, $2n = 64$. No differentiated sex chromosomes were found in urodelans, but it is concluded that here also the males are probably of the XX type. In fishes, too, attempts to differentiate sex chromosomes have been unsuccessful, but there is clear genetic evidence for an XY pair in the males of *Lebistes* and that in *Aplocheilus* also the males are genetically heterogametic for sex. On the other hand, in *Platypœcilus* the evidence is decisive that the female is the heterogametic sex.

Insect Pollinators of Orchard Trees. The sterility of fruit trees is a widespread evil. One sees many unproductive trees, especially in small orchards, in all parts of Great Britain. Many of the factors which affect sterility, such as genetic constitution, the nutrition of the tree and the influence of the grafted stock, are being investigated in several research stations. Mr. G. Fox Wilson has studied the actual mechanism of pollination as effected by insects. ("Pollination in Orchards", *J. Roy. Hort. Soc.*, 58, pt. 1, 125–138, Feb. 1933). He describes many species of insect visitors to hardy fruit trees, and, in the paper under review, outlines the pollinating habits of some of them. Many valuable suggestions are given for the planning of the orchard so that maximum pollination may result. It is shown, for example, that humble bees will not visit currants and gooseberries planted in the neighbourhood of cherries. Many of the wild species of pollinating insects visit the edges, but not the centre of a large orchard, and it is recommended for the fruit-grower to make quite sure of fertilisation by placing hives of bees here and there amongst the trees.

Nitrogenous Manuring of Legumes. The question of using nitrogenous fertilisers on leguminous crops like peas, beans and lucerne, has been much discussed of late on the Continent. What has generally been considered the best practice in Great Britain and elsewhere is to restrict their use to a young crop, the growth of which needs accelerating; otherwise they are uneconomic. The opinion is, however, fairly widespread that fertilisers containing readily assimilable nitrogen are distinctly harmful to the nitrogen-fixing activities of the nodule bacteria; and it was this contention that induced H. Burgevin, director of the Station Centrale d'Agronomie at Versailles, to investigate the question (*C. R. Acad. Sci.*, Paris, **196**, 441–3; 1933; and *C. R. Acad. d'Agric. de France*, **19**, No. 6; 1933). Soya beans were grown in naturally sterile soil contained in pots, one series being inoculated with a culture of *B. radicicola* specific to the soya bean, and the other left sterile. In addition to a basal dressing of phosphate, potash and chalk, inorganic nitrogen in the form of nitrates and ammoniacal salts was applied in dressings equivalent to 0, 45, 90, and 135 lb. of nitrogen per acre (or to 0, 2, 4, and 6 cwt. per acre of sulphate of ammonia); and it was found that the plants in the sterile soil that had received nitrogen developed proportionately to the amount of nitrogen applied, although their leaves turned perceptibly yellow. In every case the inoculated plants did best, and not only did they not suffer from the presence of the added nitrogen, but also they utilised it to advantage, as well as the nitrogen fixed by the bacteria. Even the highest applications of added nitrogen did not injure the nitrogen-fixing power of the nodule bacteria; so that the use of small dressings of nitrogenous fertilisers for legumes, to assist their early growth, if necessary, appears fully justified.

Canadian Minerals of the Rare Elements. H. V. Ellsworth has prepared an invaluable and highly interesting report on the rare-element minerals of Canada (*Econ. Ser.* No. 11, Geol. Sur. Canada, 1932, pp. 272). The elements dealt with are uranium and thorium and their associated transformation products; tantalum; columbium; zirconium; hafnium; beryllium; lithium; rubidium; and cæsium; all of which occur as constituents of minerals found in pegmatites. Chapters on these are followed by others devoted to the geological setting of the minerals and their occurrences in Canada, and to radioactivity and radioactive minerals as indicators of geological age. The report concludes with a record of all the chemical analyses of Canadian rare-earth minerals that have so far been made. One major object of the survey has been to study all the known occurrences with the view of ascertaining the feasibility of commercial exploitation, and determining the most favourable indications that might be useful to the prospector in searching for these minerals. Another important consideration was concerned with the possibility of correlating igneous rocks, the age relationships of which could not be determined by ordinary geological methods. The Besner uraninite, for example, which occurs in a pegmatite cutting granite-gneiss of probably Killarney age, has a lead ratio of 0·11, whereas many of the pegmatites of the Laurentian-Grenville area carry uraninites having an average lead ratio of 0·155. The radioactive method thus supports the probability that some of the granites are of Killarnean age and provides a means for distinguishing them from those of Laurentian age.

Everyday Photometry with Photoelectric Cells. Johann Heinrich Lambert, one of the pioneers of illuminating engineering, in his book "Photometria" (Augsburg, 1760) regrets that there is no instrument analogous to a thermometer which might be used for the direct measurement of illumination. In his paper on photometry read recently to the Illuminating Engineering Society, Dr. J. W. T. Walsh shows that such a photometer has now been invented, although not yet quite fully developed. There are three classes of photoelectric cells used with this type of photometer: the Elster-Geitel, the selenium and the photovoltaic or rectifier cell. The ideal photoelectric cell would provide a current which was strictly proportional to the illumination at the cell for all values of this illumination, no matter what the colour of the light, its angle of incidence or state of polarisation. In addition, the strength of the current should always be the same for the same illumination. Unfortunately, none of these requirements is satisfied in any of the cells available for practical work. In the case of the gas-filled Elster-Geitel cell and the selenium cell, proportionality between current and illumination can only be assumed over a limited range. With other types it is possible by careful design to obtain a close approximation to the desired linear law. In some types the error does not exceed two per cent. Colour sensitivity presents a difficult problem. No cell responds to the various wavelengths in the visible spectrum in precisely the same way as the human eye does. Colour filters have been used to correct this but they produce a serious loss of sensitivity. Photoelectric methods, therefore, can only be employed in high precision work when the lights to be compared have almost exactly the same spectral composition.

Fatigue-Resisting Properties of Aluminium Alloys at High Temperatures. In a paper read at the March meeting of the Institute of Metals, Mr. J. W. Cuthbertson extended the study of the rapid determination of the fatigue limit by his modification of the load-deflection test to aluminium and its alloys. In comparing the results with those obtained by the normal long-time endurance test, it is shown that the average of the results is ± 7·5 tons per sq. in. in the latter case against ± 7·9 with the load-deflection test. The extreme range of values obtained in the two cases was ± 2·0–10·6 and ± 2·1–10·7 tons per sq. in. respectively. The agreement is thus quite good. In the author's opinion, if 10 per cent be deducted from the results given by his rapid test, the fatigue limits so found will be well on the safe side and agree satisfactorily with those of the endurance method. The materials examined consisted of commercial aluminium, duralumin, 'Y' alloy and the complex alloy known generally as 'R.R. 56'. At temperatures up to 250° C., the fall in the fatigue limits of the alloys is not great; duralumin, for example, which has a fatigue limit at room temperatures of ± 9·2 tons per sq. in., having at 220° C. a limit of ± 8·2 tons. Even at 300° C. the reduction is not excessive, but above about that temperature the fall becomes distinctly more rapid. Some most interesting observations are made on the 'creep' of these alloys at high temperatures under alternating stress. Under a constant skin stress of ± 6·5 tons per sq. in., all these alloys show just above 300° C. a marked increase in the rate of 'creep'; this, therefore, represents the maximum temperature to which load-deflection tests can be regarded as reliable.

Measurement of Volatility Range of Lubricating Oils. Messrs. R. N. J. Saal and C. G. Verver have given considerable attention to this matter and brought their results to the notice of the Institution of Petroleum Technologists at its meeting on April 11, 1933. The authors conclude that there are serious objections to an analytical vacuum distillation for these higher boiling-point products in that lubricating oils of various origins show signs of decomposition at about 320° C. and at 375° C. cracking is noticeable. Vacuum distillation methods render the use of direct heating essential, which entails a variable temperature; indirect heating is a condition which the authors claim is a *sine qua non*. The usual type of vacuum distillation is necessarily more or less arbitrary, giving results depending upon the existing degree of dephlegmation. Rigid standardisation is essential if reproducible results are to be obtained. Vacuum distillation also involves complicated apparatus and admittedly requires much attention and manipulative skill. To obviate these difficulties, steam distillation at a constant temperature is proposed and the authors gave a good account of the apparatus, procedure and results obtained by this method. They claim to have eliminated all the above objections to vacuum distillation by regulating conditions of test in such a way that there is substantially complete saturation of the steam with oil vapour and no dephlegmation occurs, and that their process of indirect heating by means of a bath of high specific conductivity is eminently satisfactory. It would seem that, as a result of their work, the measuring of the volatility range of lubricating oils and other high boiling-point petroleum fractions is no longer a purely empirical procedure, but a highly refined method giving concordant and comparable results.

Astronomical Topics

Comets. The periodic comet Giacobini-Zinner was detected by Prof. R. Schorr at Bergedorf on April 23 at $1^{h}\ 56{\cdot}4^{m}$ U.T., in R.A. $21^{h}\ 34^{m}\ 4^{s}$, N. Decl. 15° 18′, Mag. 15. Being the third discovery of the year, it is 1933 *c*. The deduced time of perihelion is about July 15·4. The ephemeris in the Handbook of the British Astronomical Association for 1933 will suffice to follow it, if three-quarters of the given corrections for *T* one day later be applied with reversed signs.

This is the fourth observed apparition of this comet; it was seen in 1900, 1913, and 1926. It is of special interest from the fact that its orbit makes a near approach to that of the earth; a shower of the meteors belonging to its system should be looked for in October next. The earth passes the comet's descending node about 8 p.m. on October 9.

Geddes's comet remains an easy object, and has a tail ½° in length. An ephemeris for the whole year is in the B.A.A. Handbook.

Mr. J. C. Du Pui of Utrecht has published a very careful study of the orbit of comet 1917 III, discovered by Prof. M. Wolf on April 3, 1916, and observed for twenty-two months. The systematic errors of the observers are determined, and the positions and proper motions of the comparison stars deduced from all available sources. The following are the elements:

T 1917 June 16·5694 G.M.T.

$$\left.\begin{array}{ll}\omega & 120^\circ\ 37'\ 21{\cdot}4''\\ \Omega & 183\ \ 17\ \ 44{\cdot}3\\ i & 25\ \ 40\ \ 10{\cdot}8\end{array}\right\}\ 1917{\cdot}0$$

$\log q$ 0·226974

Period 193,100 years.

There is clear evidence of departure from a parabola. The aphelion distance is 6,682 units.

Sunspot Areas and Numbers for 1932. A résumé of the solar activity for the year 1932 appears in the February issue of the *Monthly Notices of the Royal Astronomical Society*. The mean daily area of spots (corrected for foreshortening), derived from solar photographs measured at Greenwich, was about 165 millionths of the sun's hemisphere as compared with 275 millionths for the previous year. The number of spots decreased in about the same ratio. Three groups of sunspots exceeded 500 millionths in area, the respective times of central meridian passage being April 25·4, November 16·2, December 13·0. A number of smaller groups, however, showed activity when examined in hydrogen light (Hα). All forms of prominence activity showed a considerable decrease below the 1931 values. It would seem that the solar minimum will be reached very shortly, but as yet no definite signs have appeared of high latitude sunspots which indicate the final phase of the completed 11-year cycle and the commencement of the new.

In *Astronomische Mitteilungen* (No. 130), the Director of the Federal Observatory, Zurich, publishes the relative sunspot numbers for 1932 derived from more than fifty collaborating observers. The mean number, *R*, for the year is 11·1 as compared with 21·2 for the previous year.

The Variable Star Delta Orionis. It has for some time been known that this star, the top star of the belt, is an eclipsing variable star with a very small light-range. Dr. J. Plassmann (*Astr. Nach.* No. 5931) now discusses the light-changes from 1881 to 1932; he finds evidence of small secular changes in the light-curve. The highest maxima occurred in 1913 and 1914, the lowest minima in 1895 and 1896, the extreme range between these being 2½ of his steps. He does not give the equivalent in magnitude. He notes that recent observations indicate a diminution of the epoch in the published elements by about a tenth of a day, also that the interval from minimum to maximum is about a day, and that three minor waves show themselves on the light-curve, somewhat resembling those found in stars of the Delta-Cephei type. He promises fuller details in a later paper.

Amino-Acids, Proteins and Proteolytic Enzymes*

By Prof. Max Bergmann, University of Dresden

I

APPROXIMATELY twenty-five amino-acids are generally recognised at the present time as constituents of proteins. It is usually assumed that the amino-acids are linked together in the protein molecule by condensation of the carboxyl group of one amino-acid with the amino group of the next with elimination of water to form an amide or peptide linkage; of such linkages the protein molecule contains very large numbers.

It has been calculated that the number of known amino-acids is fully sufficient to account, by variations in the order in which they are combined, for the existence not only of the clearly differentiated fundamental types of protein but also of the enormous number of individual proteins which are required by biological and immunological theory.

Such an arithmetical calculation is, however, no longer satisfying; we desire to know more precisely what is the influence of the nature of the component amino-acids and of the order in which the latter are combined upon the properties of the protein as a whole. One might anticipate, for example, that the action of proteolytic enzymes on a given peptide linkage would be determined by the properties and arrangement of the amino-acids of which the peptide is built up; it is impossible, however, to regard the properties of a protein as a simple summation of those of its constituent amino-acids.

The remarkable stability of the amino-acids is usually ascribed to their zwitterionic nature, from which results their capacity to form internal salts; the immediate neighbourhood of oppositely charged ionised groups must indeed exercise a dominating influence on the behaviour of the amino-acids. It is therefore to be expected that we shall modify the properties of the amino-acids, and in particular their chemical behaviour, if we combine the ionisable groups in peptide linkage and thereby alter their mutual electro-chemical effects.

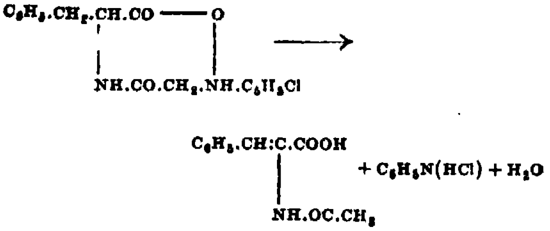
The outstanding problem of modern protein chemistry is thus twofold in nature: What effect does combination in peptide linkage exercise upon the different amino-acids? And how is the nature of the peptide linkage itself influenced by the character of the amino-acids which take part in its formation? Although work on both aspects of this question is still in an elementary stage, a number of facts have already been revealed which are significant both from a chemical and a biochemical point of view.

In the first place, I should like to show by a few examples that we can reveal a new series of chemical properties of the amino-acids if we convert the latter, by simple acylation of the amino group, into a condition analogous with that in which they exist in peptides. The simplest case is that of acetylation; if we acetylate the amino group of an optically active amino-acid, we find that contact with a small amount of acetic anhydride at the ordinary temperature is sufficient to catalyse the rapid racemisation of the acetylated amino-acid[1]. The striking ease with which this racemisation occurs must be ascribed to an intermediate enolisation:

$$\mathrm{R.CH(NH.OC.CH_3).COOH} \longrightarrow \mathrm{R.C.(NH.OC.CH_3){:}C(OH)_2}$$

In this reaction, therefore, different parts of the same molecule which are not directly connected with one another, namely, the peptide linkage and the α-hydrogen atom, exhibit a definite mutual influence. A similar mutual influence but in the opposite sense is shown by the complete absence of racemisation when chloroacetylated amino-acids are treated with acetic anhydride under the same conditions. Such remote actions of different parts of the molecule upon one another are of special importance in enzymic processes; their investigation in model experiments makes it possible to expose properties of the amino-acids and peptides which would otherwise remain hidden and to draw conclusions therefrom as to the processes which these compounds may undergo in metabolism.

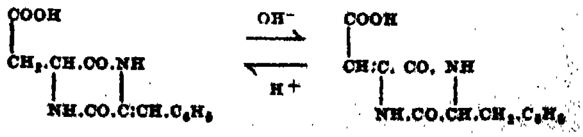
A particularly surprising example is provided by pyridylacetylphenylalanine, which is a dipeptide closely related to glycylphenylalanine; this compound, when treated with acetic anhydride and pyridine at the ordinary temperature, is converted into acetyldehydrophenylalanine with liberation of pyridine and water:



$$\begin{array}{l}\mathrm{C_6H_5.CH_2.CH.CO — O}\\ \qquad\qquad\;\; | \qquad\quad\;\; | \\ \qquad\qquad\;\; \mathrm{NH.CO.CH_2.NH.C_5H_5Cl}\end{array} \longrightarrow \begin{array}{l}\mathrm{C_6H_5.CH{:}C.COOH}\\ \qquad\qquad\;\; | \\ \qquad\qquad\;\; \mathrm{NH.OC.CH_3}\end{array} + \mathrm{C_5H_5N(HCl)} + \mathrm{H_2O}$$

The phenylalanine is thus dehydrogenated and the liberated hydrogen is employed to hydrogenate the pyridylacetic acid to pyridine and acetic acid[2]. Here, therefore, we have in one half of the molecule the first example of the direct transformation of an amino-acid into a fatty acid, accompanied by simultaneous unsaturation of the amino-acid constituting the other half to give a dehydroamino-acid. According to the theory of Wieland, a dehydrogenation of this character would require the activation of the amino-acid and the presence of an acceptor for the liberated hydrogen; the activation of the phenylalanine is brought about by its combination in peptide linkage with transient formation of a cyclic anhydropeptide whilst the pyridylacetic acid residue serves as hydrogen acceptor.

According to the prevailing view, the biological degradation of an amino-acid to a keto-acid begins with a dehydrogenation, and conversely the biological synthesis of an amino-acid from a keto-acid ends with a hydrogenation. It is possible to combine examples of both these processes in a single experiment[3] *in vitro*. The introduction of the dehydrophenylalanyl residue into aspartic acid yields a cyclic anhydride; dissolution of the latter in normal sodium hydroxide causes transference of two hydrogen atoms from the aspartic acid to the dehydrophenylalanine:



$$\begin{array}{l}\mathrm{COOH}\\ |\\ \mathrm{CH_2.CH.CO.NH}\\ \qquad | \qquad\quad |\\ \quad\;\; \mathrm{NH.CO.C{:}CH.C_6H_5}\end{array} \underset{\mathrm{H^+}}{\overset{\mathrm{OH^-}}{\rightleftharpoons}} \begin{array}{l}\mathrm{COOH}\\ |\\ \mathrm{CH{:}C.\,CO.\,NH}\\ \qquad | \qquad\quad |\\ \quad\;\; \mathrm{NH.CO.CH.CH_2.C_6H_5}\end{array}$$

---

* Substance of three lectures on "The Chemistry of Proteins" delivered at University College Hospital Medical School, London, on January 20, 23 and 24, 1933.

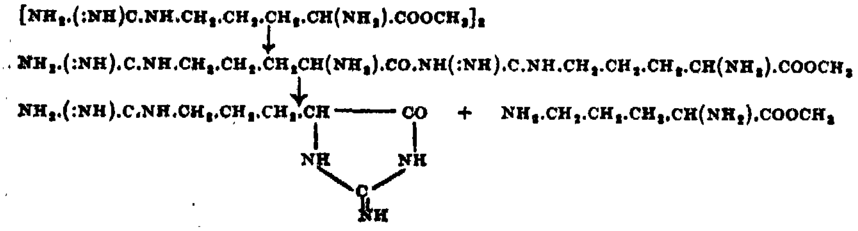
whilst in acid solution the reverse transformation may be accomplished. In the first case, therefore, degradation of the aspartic acid has begun and in doing so has completed the synthesis of phenylalanine from its unsaturated precursor. These experiments show that the hydrogenation: dehydrogenation potentials of the individual amino-acids are different; in metabolism there must indeed exist among the amino-acids a constant competition for hydrogen, the outcome of which will vary with circumstances.

By similar facile reactions it is possible to convert serine with elimination of water and cysteine with elimination of hydrogen sulphide into dehydroalanine and thence into pyruvic acid; serine and cysteine are thus brought into genetic relationship with the simple amino-acids and their nitrogen-free transformation products[4].

Of all the amino-acids, the most widely distributed is arginine, which occupies a special position also by virtue of its guanido group. Arginine can be converted into a peculiarly reactive condition by complete acetylation with simultaneous elimination of water. The triacetylanhydroarginine so formed has a strong tendency, in presence of water and of hydroxy or amino compounds in general, to lose the cyanamide residue, which is itself transferred to the accompanying compound; a mixture of sarcosine with triacetylanhydroarginine, for example, yields creatine together with a derivative of ornithine[5].

The latter result is of interest in relation to two physiological processes: (1) the creatine synthesis *in vitro* shows how creatine-nitrogen can be derived from two different amino-acids; it is probable that in the course of metabolism creatine is formed in a similar manner from two amino-acids of which one is arginine; (2) the conversion of arginine into ornithine by the enzyme arginase demands that the latter be attached to the arginine molecule in such a manner that the arginine is activated and hydrolysed to ornithine even by cold water; this process is imitated by the ease of hydrolysis of triacetylanhydroarginine to acetyl derivatives of ornithine and of urea.

There remains to be discussed yet another noteworthy transformation of arginine which has long caused confusion in the literature; if arginine be esterified with methyl alcohol, the resulting ester passes spontaneously into ornithine methyl ester and *bis*guanidovaleric acid:



$$[NH_2.(:NH)C.NH.CH_2.CH_2.CH_2.CH(NH_2).COOCH_3]_2$$

$$\downarrow$$

$$NH_2.(:NH).C.NH.CH_2.CH_2.CH_2CH(NH_2).CO.NH(:NH).C.NH.CH_2.CH_2.CH_2.CH(NH_2).COOCH_3$$

$$\downarrow$$

$$NH_2.(:NH).C.NH.CH_2.CH_2.CH_2.CH — CO + NH_2.CH_2.CH_2.CH_2.CH(NH_2).COOCH_3$$

This reaction must occur in the metabolism of those shell-fish from which Kutscher, Ackermann and Flössner[6] have isolated arcaine (1:4-diguanidobutane).

The few examples which have been given indicate what an abundance of unsuspected reactions can be elicited from the amino-acids if their zwitterionic character is destroyed by combination in peptide linkage. Almost every amino-acid is affected differently in this respect; conversely, therefore, every amino-acid must have a different influence on the peptide bond.

In order to be able to study this influence on representative material, it is necessary to prepare different peptide combinations artificially and to test the action of enzymes upon them. To carry this task to its logical conclusion would be a formidable undertaking; fortunately, however, it suffices to prepare peptides containing representative members of the most important types of amino-acids.

Chemists have striven for more than thirty years to discover suitable methods for the synthesis of peptides containing the more complex amino-acids, but until recently only isolated successes have been obtained[7]. Quite lately, however, a general method has been developed[8], the essential feature being the nature of the acid residue used to block the amino group.

The acid chloride of benzylcarbonic acid is readily obtained by the interaction of benzyl alcohol and phosgene and can be condensed with any amino-acid to yield the corresponding benzylcarbonato derivative. The benzylcarbonato-amino-acids are beautifully crystalline substances which can be easily transformed into their acid chlorides or azides and these in turn can be condensed with other amino-acids to yield benzylcarbonatopeptides. Most important, however, is the fact that the benzylcarbonato residue can be split off without the employment of a hydrolytic agent, so that it can be eliminated from a benzylcarbonatopeptide without danger of scission of the peptide bond. The removal of the benzylcarbonato residue is accomplished by catalytic hydrogenation in presence of palladium black, under which conditions the benzyl residue is eliminated as toluene and the resulting carboxy-amino derivative loses carbon dioxide spontaneously to give the free peptide. The last step of the process proceeds not only with ease but also in most cases almost quantitatively:

$$C_6H_5.CH_2.O.CO.Cl + NH_2.CHR.COOH \longrightarrow$$
$$C_6H_5.CH_2.O.CO.NH.CH.R.COOH$$

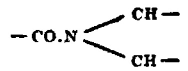
$$C_6H_5.CH_2.O.CO.NH.CHR.COCl + NH_2.CHR^1.COOH \longrightarrow$$
$$C_6H_5.CH_2.O.CO.NH.CHR.CO.NH.CH.R^1.COOH$$

$$C_6H_5.CH.O.CO.NH.CHR.CO.NH.CHR^1.COOH + H_2 \longrightarrow$$
$$NH_2.CHR.CO.NH.CHR^1.COOH + C_6H_5.CH_3 + CO_2$$

A further advantage of the benzylcarbonato method is that it involves no risk of racemisation; with its aid, in fact, the preparation of many optically active peptides, which have hitherto been practically inaccessible, becomes a trivial matter.

A complete picture of the possibilities of the new method of peptide synthesis cannot be given here, but it is possible to indicate some of the new lines of research which it opens up; in particular it may be of interest to mention certain hitherto unobtainable peptides which have been prepared by the benzylcarbonato method and to describe their behaviour towards enzymes.

As representative peptides we may mention: d-*Glutamyl*-d-*glutamic acid*, a substance with three carboxyl groups and one amino group and therefore strongly acidic in character; d-*Lysyl*-d-*glutamic acid*, the first example of a dipeptide of a diamino-acid and an amino-dicarboxylic acid ; d-*Lysyl*-l-*histidine*, a dipeptide of two strongly basic amino-acids ; l-*Asparagyl*-l-*tyrosine* and d-*glutamyl*-l-*tyrosine*, two closely related dipeptides which, however, differ remarkably in their behaviour towards enzymes (see below) ; l-*Tyrosyl*-l-*tyrosine*, a dipeptide containing two phenolic groups ; *Glycyl*-l-*proline* and d-*alanyl*-l-*proline*, which occupy a distinctive position owing to the nature of the peptide linkage :—



$$-\mathrm{CO.N}\begin{matrix}\nearrow \mathrm{CH}-\\ \searrow \mathrm{CH}-\end{matrix}$$

For comparison with these proline peptides another dipeptide in which the nitrogen of the peptide linkage is tertiary in character, namely, glycylsarcosine, has been prepared.

In the following table, the behaviour of these dipeptides is shown towards dipeptidase, towards aminopolypeptidase, and towards trypsin (that is, a mixture of proteinase and carboxypolypeptidase) :

	Dipeptidase.	Aminopolypeptidase.	Trypsin (Carboxypolypeptidase + proteinase).
d-Glutamyl-*d*-glutamic acid	+ +	—	—
d-Lysyl-*d*-glutamic acid	+	—	—
d-Lysylglycine	+ +	—	—
d-Lysyl-*l*-histidine	+ +	—	—
l-Asparagyl-*l*-tyrosine	—	—	—
d-Glutamyl-*l*-tyrosine	+ +	—	—
l-Tyrosyl-*l*-tyrosine	+ +	—	+
d-Tyrosyl-*d*-arginine	—	—	+
Glycyl-*l*-proline	—	+ +	—
d-Alanyl-*l*-proline	—	+ +	—
Glycylsarcosine	—	0	—

With glutamylglutamic acid the result is as one would expect ; this dipeptide, in spite of its strongly acidic character, is hydrolysed by dipeptidase after suitable buffering.

Lysylglutamic acid on the other hand is attacked only with difficulty by dipeptidase ; lysylglycine is readily hydrolysed by this enzyme and the same is true of the strongly basic lysylhistidine. These examples show that the preponderance of acidic or of basic groups does not interfere with dipeptidase action, since the most strongly acidic and most strongly basic dipeptides are both attacked by the enzyme. Surprising differences of behaviour between closely related compounds are exemplified by asparagyl- and glutamyl-tyrosine, of which the first is resistant to all intestinal proteolytic enzymes whilst the second is readily hydrolysed by dipeptidase.

l-Tyrosyl-*l*-tyrosine presents an anomaly inasmuch as it is hydrolysed not only by dipeptidase but also by trypsin, whilst *d*-tyrosyl-*d*-arginine is actually not affected by dipeptidase but is hydrolysed by carboxypolypeptidase.

The behaviour of the proline peptides towards proteolytic enzymes is especially illuminating. Neither glycylproline nor alanylproline is attacked by dipeptidase whilst both are hydrolysed by aminopolypeptidase ; here therefore we have two dipeptides for which dipeptidase is not the appropriate enzyme, and it becomes clear that the accepted definitions of dipeptidase and aminopolypeptidase are unsatisfactory. More important still is the conclusion which emerges from the experiments with the proline peptides that 'dipeptidase' can only attack a normal peptide linkage (.CONH.), whilst at least one constituent of 'aminopolypeptidase' can hydrolyse a peptide linkage in which the nitrogen atom is tertiary. This view is confirmed by the fact that glycylsarcosine is also resistant towards dipeptidase.

West Regional Broadcasting Station in Great Britain

IT will be remembered that a few years ago the British Broadcasting Corporation engineers evolved what is known as the 'regional scheme' for covering Great Britain with an adequate broadcasting service providing alternative programmes of approximately the same strength. According to this scheme, each part of the country is catered for by a twin-wave transmitting station radiating both a national broadcasting programme and a regional programme specially arranged for the area under consideration. The fourth station of this type is now practically complete and experimental programme transmissions were commenced on April 24. The following details of this West Regional Station are taken from an article in *World Radio* of April 21.

The station has been built near the Somerset coast at Washford Cross, two miles from Watchet and six miles east of Minehead. The site was chosen as being suitable for the provision of a good service to the important centres of population in the west of England and to South Wales in addition. The design of the station follows closely the general arrangement of the regional stations, and includes some of the modifications recently introduced at the Scottish Regional Station. Each of the two aerials employed is of the 'umbrella' type supported by an insulated lattice steel mast 500 ft. high. These two masts are illuminated at night by aircraft warning lights, which are fed through filter circuits to prevent the flow of high-frequency current in the lamp leads.

The whole of the electrical power required is generated locally by Diesel engine plant and sufficient fuel oil is stored for three months operation. For the various electrical supplies required, three of each type of motor-generator set are installed ; one of these is in use on each transmitter, while one is spare. The national and regional transmitters are similar and of a standardised type of construction comprising five separate units. Modulation is carried out at an early stage following the drive oscillator. Two stages of high-power amplification follow, while the fifth unit contains the tuning and coupling circuits for the final power stage. In each stage it is possible to switch in a spare valve without interrupting the power supply. A studio for testing purposes is fitted up in the station buildings, although the programmes will normally emanate from the

Cardiff studios. Entirely new studio premises at Bristol are now in course of erection.

The regional transmitter radiates on a wave-length of 309·9 metres, while the national programme is on 261·6 metres. The latter wave-length is already in use by the London national transmitter, and equipment is being installed by means of which the two sets may be exactly synchronised. The new service from this station will be introduced gradually in order to give listeners every opportunity of becoming accustomed to it, and of making any necessary modifications to their receivers so that they may take full advantage of the improved service.

University and Educational Intelligence

CAMBRIDGE.—Dr. M. Dixon has been appointed to the University lectureship in biochemistry, established in connexion with the scheme for the employment of the Rockefeller benefaction, and Dr. E. G. Holmes has been appointed to the University lectureship vacated by Dr. Dixon.

A. D. Thackeray, scholar of King's College, has been elected to the Sheepshanks exhibition.

LEEDS.—At the opening ceremony on April 25 of the Algernon Firth Pathological Institute, it was stated that the new building could not be brought fully into use owing to the lack of funds to equip the Museum which is essential to pathological teaching and research. Mr. Charles Ratcliffe Brotherton promptly offered £1,000, which will permit of the equipment of the Museum in a manner appropriate both to the fine architectural character of the room and to the importance of the work.

The West Yorkshire Coal Owners' Association has decided to renew its annual subscription of £1,000 to the Mining Department for a further period of seven years.

An offer by Mr. Bernard Scattergood to present to the University a transit theodolite for the Observatory has been gratefully accepted.

WALES.—The degree of D.Sc. has been awarded to Dr. Alan Edwin Bradfield, for research in the Department of Chemistry, to Miss Emily Dix, for research in the Department of Geology, and to Mr. Frederick Daniel Smith, for research in the Department of Physics.

THE University of Bristol in its report for 1931–32 makes a special appeal for the endowment of open scholarships, pointing out that at no time in the last hundred years have so many citizens suffered so severely in taxation and diminution of income and consequent inability to afford to pay for university education for their sons and daughters. Notwithstanding the national financial stringency, the University succeeded in keeping its expenditure within its income and there was no falling off in the number of its students (day 973, evening 340). Extra-mural work continued to make satisfactory progress. Among new developments mentioned are the growth of confidence of farmers, fruit growers, market gardeners, willow growers and cider and canning industrialists in the value of the University's research and advisory work, the wide utilisation of the recently organised veterinary advisory service and the establishment of a special section to deal with poultry diseases. The Italian Government placed the services of Dr. Benvenuto Cellini at the disposal of the University for the session to encourage the revival of the study of Italian, which has been re-instated as a subject for the Intermediate Examination. Appended to the report is a list of 176 publications by members of the staff, chiefly those of the departments of science, pure and applied. It is announced that the Department of Zoology is to be re-organised and a professor appointed.

Calendar of Nature Topics

Third 'Buchan Cold Spell'. The Ice Saints

May 9–14. The period May 9–14, selected by Dr. A. Buchan as the third of his six annual cold spells, includes the three days of St. Mamertius, St. Pancras and St. Gervais, May 11–13, who are associated with May frosts in the folk-lore of a large part of Europe and are generally known as the 'Ice Saints'. This supposed cold spell has been attributed to a monsoon-like inflow of cold winds from the north, caused by the rapid warming-up of Central Europe in spring, and also to the obstruction of the sun's rays by a swarm of meteors. Another legend associates the cold spell with May 17–19, the latter being St. Dunstan's Day. There are frequently large fluctuations of temperature during May, and it is highly probable that a cold spell will occur some time during the month. During the present century, Buchan's period has frequently been marked by a drop of temperature in London, but from 1871 to 1900 it was generally warm, and on the whole there is no definite bias in favour of low temperatures at this time.

Breeding of Pearl Oysters coincident with Full Moon

Two additions to the records of the association of breeding with the state of the moon, were made by the Great Barrier Reef Expedition of 1928–29. The workers, stationed at Low Reef off the Coast of Queensland, found that the only pearl oyster which grew upon their island, the 'black-lip', had, like the larger 'gold-lip' which furnishes the greatest supply of mother-of-pearl, two breeding periods in the year, at the time of full-moon in May and in November. The second case, that of the madrepore coral *Pocillopora*, was described by Prof. T. A. Stephenson in NATURE of April 29, p. 622.

Eels—an Early Hypothesis

"Their manner of breeding is very uncertaine and unknowne, but undoubtedly they are bred in the brackish or seawater: and at the first full Moone in May they begin to come into all great rivers, and out of great rivers into lesser rivers, and out of those lesser rivers into all small brookes, rils, and running waters, continually against the streame all the beginning of Sommer. . . . I know that some holde opinion that they breed of the May deaw, for proofe whereof they say if you cut up two turfes of grass in a May morning and clap the grassie sides of those turfes together and so lay them in a river, you shall the next day find small young Eeles between the sayd turfes: and so you shall indeede. . . . The reason is, at that time of the yeare that river being full of such young Eeles, they will creepe into every thing that is sweete and pleasant." (John Taverner, 1600.)

Sun-Fish in British Waters

May is the earliest month in which the sun-fish (*Orthagoriscus mola*) has been recorded in British waters, but the number of records rises throughout the summer to a maximum in September. The sun-fish is an inhabitant of the warmer parts of the open ocean and its appearance in British waters is due partly to a process of drifting in the great Atlantic current which washes our western and north-western shores, for the sun-fish appears to have limited swimming activity (see Calendar, January 7). But from an analysis of many records, Prof. D'Arcy Thompson suggests another factor in the appearance of the sun-fish in northern waters (*Scot. Nat.*, 1918, p. 46). The leptocephalus larvæ of the fresh-water eel have been found, often in multitudes, in its stomach, and are believed to form a substantial part of its food (NATURE, 93, 166; 1914). These larvæ, after their three-years journey from the western side of the Atlantic Ocean, reach British waters about the month of June, and afterwards pass round the northern coast of Scotland until they reach the eastern coasts in November and December, ready to ascend the rivers in spring. Prof. Thompson points out that there appears to be a close and even precise correspondence between this periodic annual migration of the leptocephali and the appearance of the sun-fish in British home waters. Food, therefore, would seem to be a prime governing factor in the movements of these summer invaders, and the fact that the food is drifting in the oceanic plankton gives a false impression of drift also to the appearances of the sun-fish.

Showers of Frogs and Fishes

In "The Story of San Michele" Dr. Axel Munthe makes Turi, the Lapp, tell of toads that "came from the clouds, when the clouds were low the toads fell down in hundreds on the snow. You could not explain it otherwise for you would find them on the most desolate snow-fields where there was no trace of any living thing" (p. 127). Perhaps Turi was recounting fact, perhaps he was but repeating a tradition derived from that chapter of the "Historia" of Olaus Magnus of Uppsala which in 1555 was written "Concerning the Rain of Fishes, Frogs, Mice, Worms and Stones".

Yet there are many well-authenticated records of the fall of frogs and fishes from the clouds, and the two most recent occurrences happened in the month of May. On May 15, 1900, on the outskirts of Providence, Rhode Island, a heavy downpour of rain brought with it so many living perch and bullpouts, from two to four and a half inches long, that children gathered them by the pailful and sold them; and on May 18, 1928, a rain of fishes, hundreds of them, fell on a farm in North Carolina, three quarters of a mile from the nearest water-course, which did not contain any number of fishes.

From many sources Dr. E. W. Gudger has collected, and in several papers has published the records of about seventy-one accounts of rains of fishes ranging from 300 A.D. to 1928, and from all parts of the earth. A great number of the stories come from the United States (15), but more from Great Britain (17), from the rest of Europe about 16, from Asia 19, Australia 7, South Africa, South America and the South Seas one each.

The explanation of these showers of frogs and fishes is the same in every case. High winds, particularly whirl-winds, pick up water in the form of water-spouts with such aquatic organisms as the water contains and carry them until the velocity of the air and clouds becomes relatively lowered and the organisms, alive or dead, fall to earth.

Societies and Academies

DUBLIN

Royal Irish Academy, Jan. 23. **JOSEPH ALGAR, ISABELLA M. MCCARTHY** and **EVELINE M. DICK**: The synthesis of diflavones. When diacetoresorcinol is heated with benzoic anhydride and sodium benzoate and the product is isolated without prior hydrolysis, the substance obtained is 3·3′-dibenzoyl-diflavone I (colourless needles, m.p. 292° C.). Hydrolysis of I with alcoholic potash gives yellow needles of 4·6 dibenzoylaceto-resorcinol II (m.p. 203°–204° C.) and II is converted into diflavone III (m.p. 281° C.) by heating with alcoholic hydrochloric acid. Condensation of diacetoresorcinol with anisic anhydride and sodium anisate appears to give the anisate of 7-hydroxy-6-anisoylaceto-3-anisoyl-4′-methoxy-flavone IV (pale yellow needles, m.p. 233°–235° C.). The hydrolysis of IV gives 4·6 dianisoylaceto-resorcinol V (yellow needles, m.p. 203°–204° C.) and V on heating with alcoholic hydrochloric acid gives 4′·4″-dimethoxy-diflavone VI (colourless needles, m.p. 321°–322° C.). III exhibits a brilliant blue, and VI a green, fluorescence in sulphuric acid solution.

PARIS

Academy of Sciences, March 20 (*C.R.*, 196, 821–880). The president announced the death of Jules Andrade, *Correspondant* for the Section of Mechanics. **L. CAYEUX**: The constitution of the Devonian phosphates of Tennessee (United States). The remains of echinoderms are of more importance in the Devonian phosphate rocks of Tennessee than in other sedimentary phosphates, and it is their degree of frequency which gives the fundamental characteristic of the deposit. The importance of coral in this formation has been overestimated. **GABRIEL BERTRAND** and **YÔNOSUKE OKADA**: The existence of lead in arable soil. The quantities found were of the order of 0·2 gm. of lead per kgm. of dry soil. **PAUL PASCAL** and **MME. RÉCHID**: The preparation of the dimetaphosphates. Full details of the method of preparation of sodium dimetaphosphate, free from polymers. Its distinctive reactions are given. **M. GIGNOUX** and **L. MORET**: The external structural units of the Alpine chain between the Pelvoux and Durance. **G. PFEIFFER**: The expression of a system of functions containing two parameters. **V. NIEMYTZKI**: Non-linear integral equations. **ARNAUD DENJOY**: The integration of total differentials and the metric of curves. **V. A. KOSTITZIN**: The asymptotic solutions of the differential equations of the theory of the growth of organisms. **F. E. MYARD**: A general theory of all joints transmitting rotations. **M. MENDES**: A particular case of the problem of n bodies with variable masses. **M. PICARD** and **A. STAMPA**: A new form of silver voltameter. A special form of glass cup is used to prevent particles of silver from the anode reaching the cathode. Recent determinations of the E.M.F. of the cadmium cells at the Bureau of Standards give 1·01827 international volts: using the modified silver voltameter described the author deduces the value 1·01830. **J. VERHAEGHE**: The Faraday effect of a camphor derivative. A repetition of Pfleiderer's experiments on the correlation between the magnetic and natural rotatory dispersions of diphenylmethylenecamphor. The strong anomaly found by Pfleiderer in the neighbourhood of the absorption band was not found. G. Ribaud : A solution of the problem of heterochrome photometry of incandescent lamps. A method of measuring in international candles the light-intensity of tungsten lamps without the mediation of a black body or of a filter, by a simple spectrophotometric measurement on a single wave-length. Privault : Study of the *M* level of magnetised iron. M. Valadares : The spectrography, by crystal diffraction, of the γ- and X-rays of the thorium family. N. Marinesco and J. J. Trillat : The action of ultra-sounds on photographic plates. Plates and papers sensitised with silver salts are acted upon by ultra-sounds (frequencies 428,000 and 1,435,000 cycles per second). This action is probably due to the ultra-sounds *facilitating* the *oxido-reduction* process occurring in the sensitised layer. Mme. Réchid : The plurality of the metaphosphoric acids. H. Bierry, B. Gouzon and Mlle. C. Magnan : The application of the iodometric method to the estimation of sugar in the blood. Bougault's method is applicable to the estimation of the free sugar in the plasma of blood from the horse. The results suggest that the copper-reducing power is due to an aldehydic sugar only. P. Carré and D. Libermann : The reaction of phosphorus pentachloride on the neutral aryl sulphites. The aryl sulphites react with phosphorus pentachloride giving thionyl chloride, aryl chloride and aryl phosphate : the reaction between alkyl sulphites and phosphorus pentachloride described in an earlier paper is different. Jean Décombe : The condensation of the phenols with dimethylamine and formaldehyde. Yang Kieh : The age of the two principal series of granites of the north-west of the French Central Plateau. A. Marin and P. Fallot : The constitution of the whole of the limestone chain of the Spanish Rif from Ceuta to Punta Pescadores. G. Grenet : An apparatus for determining the magnetic properties of rocks. An improvement of Chevallier's method leading to increased sensitivity. Henry Hubert : The comparison, from the point of view of the climatic characters, of the meteorological stations of the French tropical domain. Mlle. M. Friant : The regression of the upper lip in the course of individual ontogeny in the elephant. Charles Taguet : The treatment of tumours and pain by cobra poison.

Sydney

Royal Society of New South Wales, Dec. 7. C. A. Sussmilch : The association of the Tertiary alkaline rocks of New South Wales with late Tertiary tectonic lines. The akaline rocks of New South Wales lie mainly on two belts, an eastern belt and a western belt. In all cases they are situated right on the margin of, or close to, tectonic scarps produced during the Koscuisko uplift of late Tertiary age. The extinct volcanoes of the Canobolas, Dubbo, Warrunbumble and Nandewar district all lie on the western margin of the main tableland of New South Wales where it breaks away rather suddenly by faulting towards the low lying western plains. The alkaline laccolites of the Rylstone area lie along the line of east-west faulting which marks the northern margin of the Blue Mountain Tableland. The alkaline laccolites and lava cones of the Mittagong district lie on an east-west tectonic line (a monoclinal fold) which forms the southern margin of the Sydney *senkungsfeld*. The alkaline rocks of the Taree district occur along a line of monoclinal folding and faulting which forms the eastern margin of the Comboyne Tableland. The same conditions exist in south-eastern Queensland. All of these volcanic occurrences are older than the faulting but it would appear that the outbursts took place along lines of tension which had already developed before the Koscuisko Epoch of uplift actually took place. This would suggest that the volcanic outbursts, although older, are very little older than the Koscuisko uplift, which would make them of late Tertiary age. W. R. Browne : A possible correlation of certain pre-Cambrian granites of Australia and some deductions therefrom. Two periods of plutonic intrusion accompanying orogenic movement may be recognised in the pre-Cambrian of Australia. Those of the first epoch (closing *Archæozoic*) were *essentially gneissic* but without distinctive mineral characteristics : the second series (Middle Proterozoic) was of far greater extent and volume, and from their mineralogical peculiarities and associated ore-deposits it is inferred that much of Australia was in Proterozoic time a petrographical and metallogenetic region. The present distribution of these granites is taken to imply the former existence of a very wide extent of Lower Proterozoic strata in Australia, now mostly removed by erosion. A. E. Bradfield, A. R. Penfold and J. L. Simonsen : The essential oil from the wood of *Eremophila Mitchelli*. The tree is commonly known as 'buddah' and is one of the strongest scented woods of the western districts of New South Wales and Queensland. The wood yields from 2–3 per cent of a viscous dark red oil of pleasant odour and containing three crystalline substances of ketonic character. Warnford Moppett : An examination of the validity of conclusions drawn from experiments in which the allantoic membrane of the chick is exposed to X-radiation. Prepared eggs were exposed to mixed radiation generated by various potentials (90–150 kv.) and selective effects were observed. Equal incident doses were measured with a thermal radiometer. New energy estimate for homogeneous radiation is given and an investigation of dehydration infection, etc., on controls is discussed. J. C. Earl and N. F. Hall : The chemical changes involved in the formation of aminoazo-compounds. (2). Aniline nitrite. Aniline nitrite is present in methanol solutions of equimolecular proportions of aniline hydrochloride and sodium nitrite. Under the influence of acids and heat, chemical changes occur which are made evident by irregularities in the volume–temperature curves of the reaction mixture. Under carefully controlled conditions, *aniline nitrite* can be isolated in a crystalline state ; it dissolves in water, methanol or ether, and in aqueous solution readily undergoes change into diazoaminobenzene. Methanol solutions of the crystalline material with acids show the typically irregular volume–temperature curves. M. B. Welch : (1) Experiments on the daily shrinkage and swelling of wood. A series of measurements was made thrice daily over an extended period to determine the daily lateral shrinkage and swelling of six different woods exposed to varying conditions. Short sections 1 in. in length and 4 in. wide were used to obtain the maximum size variation. In inside and outside positions the maximum size variation in any one day in tallowwood, *E. microcorys*, was only 0·002 in. and 0·007 in. respectively and in Baltic *Picea excelsa*, 0·013 in. and 0·043 in., the other woods falling between these extremes. The sizes and moisture contents are correlated. (2) The longitudinal variation of timber during seasoning. Longitudinal measurements were made at regular intervals during the air seasoning of a number of woods from a green to an air dry condition. The shrinkage ranged from 0·00 to 0·26 per cent. Actually a slight swelling was found to take place in some timbers; other woods showed both shrinkage and swelling. O. U. VONWILLER: Diffraction gratings used with grazing incidence. A discussion on the use of very wide slits in a diffraction grating spectrometer when the angle of incidence is nearly 90° and the angle of diffraction small. Photographs are given of spectra of various orders from sodium flames, weak and intense, using a slit of width 1·1 mm. and collimator focal length 23 cm., illustrating expressions for the intensity, sharpness and resolving power. The effect of dispensing with a collimator is shown and discussed. A simple method, based on this effect, for making the focusing adjustment of a spectrometer, is described. WINIFRED R. MANKIN: Application of optical spectroscopy to analysis of tumor tissue. A method is described of determining qualitatively the presence of metals in a specimen of dried tumor tissue. Besides the metals iron, magnesium, sodium, potassium and calcium which are commonly known to occur in such tissue, there is evidence of the presence of aluminium, chromium, copper, lithium and strontium, manganese and zinc. Quantitative aspects of the problem are being undertaken.

Forthcoming Events

Monday, May 8

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, at 2.—C. F. White: "Port Work" (succeeding lecture on May 10).

ROYAL GEOGRAPHICAL SOCIETY, at 5.—A. M. Champion: "Soil Erosion in Africa"; G. W. Hobley: "Soil Erosion: A Problem in Human Geography".

UNIVERSITY OF LONDON ANIMAL WELFARE SOCIETY, at 5.30—(at the Institute of Education, Southampton Row, W.C.1).—Dr. R. T. Beatty (Admiralty Research Laboratory, Teddington): "The Sense of Hearing in Animals".

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY, at 6—(at the London School of Economics, Houghton Street, W.C.2).—S. E. W. Taylor: "Morale in Office Work and the Will to Work".

Tuesday, May 9

LONDON SCHOOL OF ECONOMICS, at 5.—Prof. B. Mirkine-Guetzévitch: "The New Tendencies of Modern Constitutions" (succeeding lectures on May 10 and 11).

ILLUMINATING ENGINEERING SOCIETY, at 7—(in the Hall of the Institution of Mechanical Engineers, Storey's Gate, S.W.1).—Annual General Meeting. Discussion on "Principles of Directive Street Lighting".

INSTITUTION OF CIVIL ENGINEERS, at 6.—Annual General Meeting.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—Dr. L. S. B. Leakey: "New Evidence of the Antiquity of the Kenya Forms of Aurignacian and Mousterian Cultures".

Wednesday, May 10

GEOLOGICAL SOCIETY, at 5.30.—Sir Douglas Mawson: "The Geology and Glaciation of some Islands of the Southern Ocean and the newly discovered Antarctic Mainland."

INSTITUTE OF METALS, at 8—(Annual May Lecture at the Institution of Mechanical Engineers, Storey's Gate, S.W.1).—Albert M. Portevin: "Quenching and Tempering Phenomena in Alloys".

ROYAL SOCIETY OF ARTS, at 8.—Albert Abbott: "Education for Industry on the Continent and in this Country".

Thursday, May 11

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Annual General Meeting.

Friday, May 12

CHEMICAL SOCIETY, at 4-6 and 8-10—(at the Chemistry Department, University of Leeds).—Discussion on "Substitution in Aromatic Systems". Papers by Prof. R. Robinson, Prof. C. K. Ingold, Prof. G. M. Bennett, Prof. H. M. Dawson, and others.

ROYAL SOCIETY OF ARTS, at 4.30—(Sir George Birdwood Memorial Lecture).—Sir Walter Morley Fletcher: "India and Medical Progress".

ROYAL ASTRONOMICAL SOCIETY—(George Darwin Lecture).—Dr. V. M. Slipher: "Spectrographic Studies of the Planets".

ROYAL INSTITUTION, at 9.—Prof. W. T. Gordon: "Gem Stones".

State-Aided Research in Great Britain*

THE report of the Department of Scientific and Industrial Research for the period 1931–32 contains more encouraging reading than might at one time have been expected in view of the drive for national economy exemplified in the report of the May Committee and elsewhere. The absence of spectacular results in the year under review assists in the task of appraising the work of the Department in relation to national needs and more particularly in regard to new industrial development. There can be little room for doubt that the Department has discharged its difficult task with conspicuous success and that in applying available funds to work of the most immediate practical value to industry, there has been no sacrifice in the interests of supposed economy of the essential efficiency of industrial research organisations, built up over a long period of steady and patient endeavour with the assistance of public funds. True to its firm conviction that unless industry persistently applies scientific method and scientific knowledge to its problems it cannot escape from the difficulties with which it is surrounded, the Advisory Council has at least succeeded in preserving so far as possible the organisation for the pursuit of more fundamental inquiries upon which the future of all industrial research work must depend.

Leaving on one side for the moment this question of fundamental research, the Department's own report indicates how well deserved has been the praise which has recently been lavished upon it by spokesmen of finance as well as the authoritative tributes to its organisation paid last year by the Committee of New Industrial Development of the Economic Advisory Council and by Sir Harold Hartley in his address to the Institute of Transport. These tributes are, however, to be welcomed not merely as indication of appreciation of work already done, but more especially as betokening that spirit of general co-operation upon which the work of the Department is essentially founded.

Upon this question of co-operation the Report of the Advisory Council lays considerable stress. In relation to fuel research, for example, after explaining the importance of provision for an adequate programme of laboratory work and pointing out that extensive laboratory work is the best way of developing that real understanding of root problems which may lead not merely to minor improvements in existing processes but also to suggestions for radical changes in production or in methods of utilising a raw material, the Report continues: "We were also impressed with the extent to which the research stations of the Department are bound to depend for their success upon the co-operation of industrial organisations. The most effective criterion of the value of industrial research is the extent to which its results are put into practice, but the application of the results is difficult to secure unless industry is prepared to take a real interest in the research work in progress."

---

* Department of Scientific and Industrial Research. Report for the Year 1931–32. (Cmd. 4254.) Pp. iv+193. (London: H.M. Stationery Office, 1933.) 3s. net.

No feature of the Report is more encouraging than the evidence that is afforded of such co-operation on the part of industry, of a growing realisation that the organisations of the Department are public concerns intended to promote the national welfare and the development of the industries with which they are associated. Certain of the research associations have, for example, succeeded in widening the basis of their membership by the inclusion of industrial groups which are interested either as manufacturers or users in materials discovered or improved by scientific research. Refractories research is an example in point of research which should not be left entirely to the makers of refractories to finance; and there are indeed already signs that the gas, electrical, iron and steel, coke-oven and pottery industries are more disposed to recognise such responsibility and co-operate in support of this work.

The British Non-Ferrous Metals Research Association has been conspicuously successful in this way, and the commercial possibilities of the new ternary lead alloys discovered by the Association have directly resulted in the enrolment of a large number of members from the lead manufacturing industry. Both the address of Sir Harold Hartley and the report of the Committee on New Industrial Development referred to above afford evidence of the approach of the railway companies towards research in these fields, while on the other hand the Cotton Research Association provides an example of conspicuous success attending an active liaison policy. Demonstration of the practical value of its results by sending members of its liaison staff out to mills and works in a series of more than two thousand visits in 1930–31 has given definite evidence of steadily increasing interest and appreciation of the value of scientific research through the industry as a whole.

This attempt to broaden the basis of a research association is, however, only a particular aspect of industrial research to which the Report directs special attention. While the need for research on the production of commodities is as strong as ever, even stronger is the need for research into their utilisation. In almost every industry to-day strenuous effort is directed to the application of old materials to new uses and to the discovery of uses for new materials, and such effort figures prominently in the programme of most of the research associations. Whether it is a case of finding new markets for existing products, of creating a wide demand for a commodity and thus reaping the advantages of modern methods of production, or of discovering the most suitable material for a particular purpose, it is equally important that the chemical and physical properties of the materials concerned should be fully understood.

The stress thus laid on the need of finding new uses and new markets for the products of industry not only encourages, as already indicated, the growth of a spirit of co-operation throughout industry, and particularly between user and consumer, making for better service as well as for more efficient production, but also contributes to that continued industrial development upon which the success of British industry depends. Without such continuous development under the guidance of applied science there can be little hope of survival, much less of recovery for our industrial enterprises in this era of international trade. Of the assistance given by the Department to such new industrial development the Report provides several instances, and it does not appear that the Department has failed, either in its functions of co-ordinating and acting as a clearing house of information from research associations and other organisations, or in the encouragement of the large-scale tests which form the final stage in development research.

Such limitations as have been imposed on the work of the Department in this respect are in the main financial. There has, for example, been a serious reduction in the income which the National Physical Laboratory derives from payments for tests and investigations and from contributions by industry to researches for its particular benefit. This is an unavoidable consequence of industrial depression.

These difficulties, however, are by no means the most disquieting feature of the report. In spite of signal services rendered to their respective industries, certain of the research associations have found themselves in acute financial difficulties and the termination of the activities of the Cutlery Research Association has been followed by the suspension of the activities of the Research Association of the British Rubber Manufacturers. The Department's report comments on the lamentable lack of interest displayed by the cutlery industry in its Research Association as evidenced, for example, by a decline in membership from fifty to ten firms in a couple of years. Similarly, in spite of the highly important and industrially valuable results it has obtained, the British Cast Iron Research Association has had great difficulty in maintaining its industrial income, and in keeping its work going on an adequate scale; to make the Association self-supporting a substantial grant has been made by the Department for the period July 1, 1931–June, 1933.

The position of the Research Association of the British Rubber Manufacturers is related to another aspect of this question upon which the Report also touches. The Association ceased to operate on March 1 for lack of funds. A measure authorising a levy for its support and maintenance on firms in the rubber industry had been introduced into the House of Commons, but as a private member's bill, and it failed to come before the House in time. The Government has, however, now introduced a Rubber Industry Bill in the House of Lords (see NATURE, May 6, p. 650), so that we may hope shortly to see the Association at work again. There would be something farcical in a situation in which, after the State had contributed some £35,000 to the financing of research in an industry, an effort of the industry to place its research activities on an adequate self-supporting basis should have been limited to the introduction of a private member's Bill at the mercy of the slightest opposition from an active individualist minority.

When commenting, however, on the effect of recent political, financial and economic developments, the Advisory Council expresses the earnest hope that "the protection which has now been afforded to certain industries in the home market will be regarded as an opportunity for effecting the changes in organisation, the installation of modern plant, the development of research work and the employment of educated staffs which the experience of the last few years has shown to be necessary in some industries if they are to compete on level terms with industries in other parts of the world."

This is a point of view which might well have been much more forcibly expressed. A good deal of stress has been laid, in arguing the case for tariff protection of particular industries, on the opportunity which such protection affords for research and development and reorganisation on scientific lines. It has indeed been asserted that such temporary protection should be conditional on the industry undertaking to prosecute research and development on a scale adequate to accumulate a sufficient reserve of fundamental knowledge to assist both in tiding over bad times and in meeting independently competition from abroad. Unfortunately, already some industries show signs of a false sense of ease and security leading to relaxation of much needed effort of this kind, and the comment of the Advisory Council is welcome.

It should scarcely be necessary to add that, under tariff conditions more than ever, the technical efficiency of an industry ceases to be a purely domestic matter for the industry itself. When the community has voluntarily surrendered its right to purchase without interference, the protected industry must in return take a much less individualistic view of its obligations to the community. Under such conditions the community should not be expected to be satisfied with less than the highest possible standard of scientific and technical efficiency within the industry. The Government, once it adopted a tariff policy, should have allocated a portion of the revenue thus obtained for the more intensive and extensive prosecution of research in every branch of industry; its omission to do so is a sign that it does not realise the vital importance of industrial research as a factor in national recovery. Without detracting in the least from the ability with which the Department of Industrial and Scientific Research has carried out its varied tasks or the magnitude of the results already achieved, it is still possible to feel that its representations to the Government in certain fields have not been so effective as could have been desired. It is to be hoped that the success and expansion of the various stations now maintained directly under the control of the Department will not be allowed to weaken its interest and support of a scheme of research associations which, as the Committee on New Industrial Development has pointed out, has no counterpart in any other country and represents an attempt to build up an organisation of industrial research adapted to British needs and British psychology.

An Indian Sage

Life and Experiences of a Bengali Chemist. By Prafulla Chandra Rây. Pp. viii+557+6 plates. (Calcutta: Chuckervertty, Chatterjee and Co., Ltd.; London: Kegan Paul and Co., Ltd., 1932.) 7*s.* 6*d.*

A MORE remarkable career than that of P. C. Rây could not well be chronicled. The story told is not only fascinating: it has an altogether special value, as a presentation of a complex mentality, unique in character, range of ability and experience. The caption,

> "nothing extenuate
> Nor set down ought in malice,"
> Othello.

set against the preface, is an indication of the spirit in which the book is written. In part, the study of a life overfull of action, of unusually varied occupations and interests; in no small degree, it is also a dispassionate statement and discussion of pressing, Indian, social problems; as a whole, therefore, it has exceptional value, scientific and social.

(Sir) Prafulla Chandra Rây was born on August 2, 1861. His father (born 1826), a landed proprietor, he tells us, began his career "like a country gentleman in the days of Fielding and had many traits in common with Squire Allworthy". That a Hindu should draw such comparison is remarkable, if only as proof of familiarity with a class of English literature not within even our ordinary range: the book teems with similar, often remote, literary references, showing how fully the author is possessed by the English spirit. This is accounted for by the fact that his father, who was a man of considerable culture, not only proficient in Persian—then the Court language in India—with a smattering of Arabic, also possessed a fair knowledge of classical English literature, acquired at Krishnagar College, under the principal, Capt. Richardson, a pioneer educationist in Bengal and author of "Lives of the British Poets"—a book Rây speaks of as "a priceless heirloom which he has read over and over again". A now surprising item of information he learnt from his father, when almost a child, he tells us, should be here mentioned, "that beef-eating was quite in vogue in ancient India and that the very word for 'guest' in Sanskrit is 'Goghna' (one in whose honour the fat cow is killed)".

Up to nine years of age, Rây was educated at his father's village school; in 1870, the family removed to Calcutta. We learn incidentally that, at that time, water-works had just been completed, so that the town enjoyed the blessing of a liberal supply of properly filtered, drinking water, which, however, the orthodox Hindu long refused to make use of "as being impure".

In 1874, Rây suddenly fell a victim to severe dysentery. Previously of robust constitution and healthy, the disease left him a permanent valetudinarian, a victim of sleeplessness and obliged always to subject himself to a strict dietary regimen and discipline. This makes the great activity he has displayed, throughout his life, all the more remarkable. During the two years he was away from school, he indulged in an orgy of reading. It is more than interesting to note how the Indian duck took to the water of an English classic literature. With such example before us—and India furnishes not a few—we might well try the experiment if it be possible to train English youth by close study of our English literature, leaving all classical study to a post-graduate period—*pace* the former headmaster of Westminster School: 'Oh, English—it's their own language!' Struck by the similarity between Sanskrit and Latin, he made a study of the latter, without the help of a teacher, gaining a passable knowledge of this language and of French. Sanskrit he learnt as a matter of course. Later, in carrying on his final studies in arts, he also attended lectures on chemistry and on physics at the Presidency College. He came under my student friend the late Sir Alexander Pedler and was greatly attracted by his manipulative skill: almost unconsciously he began to acquire a predilection for chemistry. Besides sitting for the B.A., he prepared privately for the Gilchrist scholarship examination and was ultimately one of the two Indian winners.

Rây left for England in August 1882 and entered the University of Edinburgh in the following October. His subjects of study were chemistry, physics, botany and zoology. In chemistry, he came under Crum Brown, of whom he speaks as "now growing indolent and fat" but he adds, "He revelled in speculation and every student of organic chemistry must be grateful to him for the graphic formulæ which he introduced, which considerably helped the progress of our science." However, he learnt to esteem him and the atmosphere was such that he became passionately fond of chemistry. He had Hugh Marshall, Alexander

Smith and James Walker as fellow students; J. Gibson and L. Dobbin were the assistants.

Rây's studies for the B.Sc. were interrupted, for a time, when an announcement was made that a prize would be given for the best essay on "India before and after the Mutiny". He read hard and very widely for this and discovered that he had the faculty of writing with some facility. Although not successful, his essay and another's were bracketted *Proxime accesserunt*; in it, 'he indulged in many bitter diatribes against British rule'—the child was already father to the man. The interruption was only temporary; the essay written, he gave himself up heart and soul to chemistry and gained his doctorate in the inorganic branch. As Hope prize fellow, he took part in the laboratory teaching and claims to have given Hugh Marshall a cobalt salt, which he had prepared, for analysis, which led Marshall to his well-known important discovery of persulphates. He tells of having asked the advice of Prof. Dittmar, a former assistant of Crum Brown, whether he should follow the example set by James Walker in taking up physical chemistry. The reply was—"Be a chemical chemist first!" Many more than know it have cause to rue the fact that such advice has not been theirs and followed. The argument applies equally to the more modern craze biochemistry.

Rây has much to say of the Scottish student's life. Living was cheap. A substantial penny breakfast was by no means uncommon: oatmeal porridge and milk. He recalls Carlyle's account, showing how boys in his day were sent to the University at fourteen and left to fend for themselves—living on the simplest fare from their farm homes and protected by poverty from vicious amusements. Some of us think that it may be well to restore such conditions—if education is to be of value as a preparation for life—if we are to recover our social balance.

At the end of six years, Rây returned to Calcutta, in the summer of 1888. After a year, he secured a professorial post at the Presidency College, Calcutta, becoming a junior colleague to Prof. Pedler, whom he ultimately succeeded. It is a noteworthy fact, showing the innate practical bent of his nature—on which he dilates—that, as soon as he had spare time, he began to work on butter and mustard oil, the two sources of fat in the dietary of the masses in Bengal; this occupied him during nearly three years.

He also engaged in social service. Troubled by the poverty of Bengali literature, on the scientific side, he wrote a primer on zoology, recognising that nature study offers more attractions to the juvenile mind than chemistry. His practical instincts then led him to add to his professorial activities that of a chemical manufacturer and ultimately to establish the Bengal Chemical and Pharmaceutical Works, Ltd. The firm at present employs 2,000 hands. It was a substantial organisation when I visited him in 1914.

A new laboratory for the Presidency College was begun in 1892 and first occupied in July 1894. In 1896, Rây became famous through his discovery of mercurous nitrite, a compound of unexpected stability. The study of the nitrites became his life work in the laboratory and was pursued by him so persistently that the myopic in our Chemical Society almost came to regard him as a public nuisance. He quotes, in this connexion, remarks I made when visiting the Presidency College in the autumn of 1914—"The way in which you have gradually made yourself 'master of nitrites' is very interesting and the fact that you have established, that, as a class, they are far from being the unstable bodies chemists had supposed, is an important addition to our knowledge." As an example of thoroughness his work on the subject stands apart.

He took care from the beginning, however, unlike most European workers, to divide his time equally between the study and the laboratory. After years of severe literary labour, he produced his well-known "History of Hindu Chemistry"—a work which has won universal praise, especially from Berthelot. As he rightly remarks: "English chemists as a class are rather indifferent to the history of chemistry and since the days of Thomson scarcely a single authoritative work on the subject has been written in English by any one of them. They have, in fact, contented themselves with simply translating Ladenburg's or Meyer's treatise dealing with the subject." The University of Durham stands out in having given Rây an honorary D.Sc., in 1912; in conferring the degree, the Vice-Chancellor spoke of his fame chiefly resting upon his monumental history of Hindu chemistry.

In 1916, he retired from the Presidency College to join the newly founded University College of Science. He had done a great work there.

From 1921 onwards, he has been much drawn into educational and political movements, in which he has been a leader. He has also played a leading part in organising relief works against famine and floods. Half the book is devoted to discussion of these activities. The account is worthy of the closest study by those who are interested not only in the future of India but also in the larger problem of education, in general, in relation to the practical needs of the taught.

Our recognition of Râу's services, as chemist, as teacher, as historian and as founder of a great national school of scientific inquiry, is long overdue —it is nothing short of a reproach to our Royal Society that it should hitherto have been so narrow in its outlook as not to include his name in the roll of fellowship.

Often severely critical, Sir P. C. Râу is undoubtedly anti-English in his present sympathies —but he is mainly so on account of his greater sympathy with his fellow Indians—and his criticisms are constructive. He has much to say of faults in the drainage system and is a strong advocate, with Gandhi, of the return of the spinning wheel, in place of the textile factory, in order to provide work for idle hands to do during the long period of unemployment between crops—a problem which we should consider. He deprecates the insane craze for university education—a disease to which we also are subject—finding great fault with the system. His views are summarised in the statement—Western civilisation is our ruin; we are on the way dimly to foresee that it may be ours. Nothing can compensate for lack of proper occupation and substitution of the machine for the man.

From beginning to end, the message of the book is one of the highest endeavour, pulsating with vitality and intellectual force. Few pages are without proof that the author is steeped in our best traditions, no mere nationalist. Full of hope for the future, he ends by saying:

"There is no reason why the Bengali, or for the matter of that, the Indian, should lag behind and not fulfil his destiny. I almost hear the echoes of the organ voice of the author of *Areopagitica*, '*Methinks I see in my mind a noble and puissant nation, rousing herself like a strong man after sleep and shaking her invincible locks.*' "

A man who begins with Othello and can thus end with Milton must be one with ourselves: ultimately, such a spirit cannot be at variance with ours and our joint task should be to strive to work together in fullest harmony of purpose—as complementary parts of one nation.

HENRY E. ARMSTRONG.

A Symposium on Science

Science in the Changing World. By Thomas Holland, H. Levy, Julian Huxley, John R. Baker, Bertrand Russell, Aldous Huxley, Hugh I'A. Fausset, Hilaire Belloc, J. B. S. Haldane, Oliver Lodge. Edited by Mary Adams. Pp. 286. (London: George Allen and Unwin, Ltd., 1933.) 6*s*. net.

IT cannot be said—if we listen-in to the programmes broadcast by the British Broadcasting Corporation—that the British public is ill-provided with views as to the leading questions which exercise the public mind. The volume referred to above, a collection of talks, is an admirable example of a great subject, fairly treated by competent speakers on all its main sides. They have all the character of clear and interesting exposition; they are well arranged and answer one another so far as is possible in this form of discussion; they are summed up and reconciled by the greatest master in this art, Sir Oliver Lodge. The gist of the volume is, of course, the enormous importance of science in the contemporary world and its possibilities for the future good of society, if we know how to make use of it rightly. Only two, what may be called negative, voices are admitted, Mr. Hugh Fausset's and Mr. Hilaire Belloc's. They say some wise words which are in substance complementary to the main theme, and are duly appreciated as such in Sir Oliver's concluding chapter.

Those who look for information and definite fresh views will find most of them in the two sections contributed by Prof. H. Levy and Dr. J. R. Baker. They were allowed the larger space and made excellent use of it. Prof. Levy, giving again the point of view developed in his "Universe of Science", with some lively detailed illustrations drawn from an aeronautics research laboratory, describes the general scope of science and the procedure of the scientific investigator. He has six chapters. Dr. Baker, in four, gives a masterly and delightful account of man's biological position, comparing him with the other primates, and summing up the main stages, which in the present century have re-created for us on an unassailable scientific basis the early human type which stood just above the apes. This particular section will probably be found the most useful in the book for those who desire a clear statement of a profoundly interesting advance in scientific thought, unencumbered by the multitude of facts, names and classifications which generally accompany it.

There is one section of the book which is calculated to set people thinking on lines which reach rather further than the rest, indeed raise the deepest questions which may be suggested by the title. This is Prof. Julian Huxley's paper on "Man and Reality". He takes up the now well-known point connected with the name of Sir James Jeans—rather an *obiter dictum* when it was first uttered—that mathematical analysis seems to lead us to the idea of a mind of mathematical quality as the creating force in the universe. Prof. Julian Huxley, speaking as a biologist, replies that to him mind is an integral part of the universe, that something of the nature of mind must inhere in the essence of things. In this case the general conclusion would be that "the pressure of circumstances", what other thinkers have called the action of the "life-force", has driven mind to become more and more important and elaborate, until finally in man it has become self-conscious and the most important single characteristic of the most important embodiment of the life-force. This is Prof. Huxley's thesis, slightly paraphrased. We stress it here in contrast with the creative mathematical idea as the most profound and general topic which arises from the subjects treated in this symposium.

Those concerned with philosophical thought and teaching at the universities may well reflect on the need of coming more closely to grips with questions which go to the root of our view of the universe and man's position and prospect in it. The eager response which greets the occasional utterances of thinkers like Jeans and Eddington when they let themselves go, indicates clearly the public demand for guidance. It cannot be said that so far English philosophers as a whole have realised the need, or striven seriously to qualify themselves to meet it. F. S. MARVIN.

Reflexology

General Principles of Human Reflexology: an Introduction to the Objective Study of Personality. By Prof. Vladimir Michailovitch Bechterev. Translated by Emma and William Murphy from the Russian of the 4th (1928) edition. Pp. 467. (London: Jarrolds Publishers (London), Ltd., 1933.) 21*s*. net.

BRITISH and American workers in psychology owe a debt of gratitude to the translators and publishers of this book for making accessible to them the life-work of the late Prof. Bechterev. Although somewhat overshadowed by the greater international reputation of Prof. Pavlov, Bechterev is an important and influential figure. He taught the essentials of behaviourist doctrine before the American school of behaviourists was born, and yet avoided some of the more indefensible exaggerations of J. B. Watson and his followers.

The essence of Bechterev's method is the abandonment of all reference to conscious processes, and the investigation only of reflexes and behaviour. Such non-subjective study has, in fact, added much to our knowledge of human psychology, not only as used by Bechterev and the behaviourists but also in the hands of other psychologists, since none but eccentrics resemble the 'subjectivist' of Bechterev's criticism in interesting themselves only in states of consciousness.

Every method of attack is justifiable in psychology if it leads to fruitful results in increased knowledge of human behaviour and thought. Every method becomes dangerous when its advocates begin to claim that it is the sole scientific method in psychology. Bechterev was convinced not merely that he was founding a new science but also that this was the only science of human personality and behaviour. The value and interest of many of the experiments of Bechterev and his followers must not blind us to the extravagance of this claim. Bechterev's work is indeed not free from the defects of prescientific psychology —such as anecdotalism and speculation. The fourth chapter, on energy, is a bad example of unscientific vagueness. He is content to define energy as "movement", he says that the "thing-in-itself" is merely "potential energy", and speaks of the energy of a nervous current as being "transformed into the molecular energy of the muscles".

The making scientific of our knowledge of human behaviour and thought is not to be accomplished by narrowing the field of study to reflexes and other externally observable data, and leaving the field of conscious data to uncontrolled speculation, but by the application to the widest possible range of psychological data of the proved methods of science—exact observation and experiment, measurement wherever this is possible and the sceptical testing of numerical results by statistical methods. To this desirable end, Bechterev's reflexology seems to have made a lesser contribution than might have been hoped.

R. H. T.

Short Reviews

Annual Reports on the Progress of Chemistry for 1932. Vol. 29. Pp. 344. (London: Chemical Society, 1933.) 10*s.* 6*d.* net.

THE appearance at the end of each February of the "Annual Reports on the Progress of Chemistry", issued by the Chemical Society, is naturally an event of some importance in the chemical world. The value of this publication is not, however, restricted to chemists, but is apparent to those who are interested in almost any of the natural sciences. This year the report on general and physical chemistry is the joint work of Mr. E. J. Bowen, Mr. C. N. Hinshelwood, Dr. N. V. Sidgwick, Dr. H. W. Thompson, and Mr. J. H. Wolfenden, each of whom has written one or more of the nine sections: general; the 'true' degree of dissociation of strong electrolytes; the thermochemistry of electrolytes; quantum mechanics and electrochemistry; chemical kinetics; photochemistry; flames and the mechanism of chemical change; the structure of simple molecules from spectroscopic, X-ray, and electron diffraction data; and general stereochemistry. Prof. H. Bassett again reports on inorganic chemistry, Dr. J. J. Fox and Mr. B. A. Ellis on analytical chemistry, Mr. A. G. Pollard and Mr. J. Pryde on biochemistry. The reports on organic chemistry are on this occasion contributed by Dr. E. H. Farmer (aliphatic), Dr. G. A. R. Kon (homocyclic) and Dr. H. King (heterocyclic). The report on geochemistry by Mr. A. F. Hallimond covers 1931 and 1932, whilst that on radioactivity and sub-atomic phenomena, by Dr. A. S. Russell, is also a two-year report.

So much of fundamental importance and of general scientific interest is discussed that a short review can give but little idea of the subjects examined. As he turns over the pages and sees references to the hydrogen isotope of mass 2, to an announcement that krypton combines with chlorine and bromine, to the reaction $\mathrm{Li}^7+\mathrm{H}^1=2\mathrm{He}^4$, to the discovery of the neutron, to evidence for the existence of elements 85 and 87, and to equally solid, although less spectacular, advances in organic and biological chemistry, it becomes evident to the 'ordinary man of science' who desires to keep abreast of progress in the chemical branch that this is just such a series of appreciations as he needs. A. A. E.

Physikalisch-chemisches Taschenbuch. Herausgegeben von C. Drucker und E. Proskauer. Band 1. Pp. viii+546. 29 gold marks. Band 2. Pp. viii+481. 17 gold marks. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1932–1933.)

THE two volumes of the "Physico-Chemical Pocket-Book" are actually small enough to be carried (one at a time) in the pocket; but they include more than 1,000 pages of well-illustrated text and will cost the English buyer more than £3. The text is divided into nine sections as follows: structure of matter, optics, electricity, magnetism, micromechanics (molecular physics), macromechanics, chemical statics and dynamics, heat, systematics of inorganic and organic chemistry. The various sections have been divided amongst a team of some forty-eight writers, several of whom are well-known authorities on the subjects which they handle.

It is difficult to assess the value of such a publication, apart from experience of using it over a considerable period of time. In particular, it does not contain the tables of data that one expects to find in a chemists' pocket-book (for example, no values of Sugden's atomic and molecular parachors are included in the text); it consists rather of a series of brief reviews of our present knowledge of various branches of physical chemistry, and of the methods of measurement which are now in use, with the relevant equations for applying them. A teacher who knows the book well might therefore find it useful to refer his students to particular sections; and a student who has not time to master one of the longer treatises on physical chemistry might find it useful to survey the field with the help of this 'small-scale map'; but in general the book may very well be added to one's collection, in order to compete with neighbouring volumes of abstracts, annual reports, monographs, textbooks and treatises as a means of information and as a pointer to the original sources.

The Proper Study of Mankind. By B. A. Howard. Pp. 254. (London: Ginn and Co., Ltd., 1933.) 3*s.* 6*d.* net.

THE headmaster of the Addey and Stanhope School has written an excellent short book on a fascinating topic. Perhaps too it is the most important which faces those who have to train young people for their work in life. How are we to accommodate our teaching of history, morals and religion to the new views of man's early history and evolution?

One must believe that the change will be in the long run strengthening and stimulating, as Mr. Howard makes sufficiently clear in his book; but the transition, the way of pouring in the new wine, calls for very careful thought, and it has not yet come into the range of current and popular discussion. Hence the very interesting, open-minded and high-thinking treatment of the subject in Mr. Howard's volume is specially welcome. Darwinism is assumed as the starting point and its implications fully explored. The stress is rightly laid on the necessity of treating the life-process as one continuous thing of which man is the highest known manifestation, and the fact that man's mind is the supreme factor in the analysis of the evolution occupies the largest part of the author's small space. How our thinking may be made more effective and reliable is the subject of the concluding sections, and a syllabus, sketching the whole and suggesting points for discussion with a class, is appended.

It is an extremely careful and useful piece of work. If one general critical impression may be added, it is that the tone leans rather more than is necessary towards a gloomy view of the present world-situation and its dangers. F. S. M.

The Flint Miners of Blackpatch. By J. H. Pull. Pp. 152 + 8 plates. (London: Williams and Norgate, Ltd., 1932.) 10*s.* 6*d.* net.

BLACKPATCH, a prehistoric mining site on the Sussex Downs, was discovered by Mr. Pull ten years ago, and since then, with the assistance of Mr. C. E. Sainsbury, he has devoted himself to its excavation. It lies in the middle of a stretch of downland, extending from the Adur to the Arun, which teems with evidence of prehistoric man, including Cissbury and Chanctonbury Rings. Seven mine shafts, twelve burial mounds, four chipping-floors and several pit-dwellings have been excavated; but much more remains to be done before the history of the site can be completely elucidated. It is evident that the site was mined under the influence of the round barrow people, though it is a matter of doubt whether some of the shafts may not have been mined in pre-round barrow times. The exact date of the mines has not yet been determined, though it is probable that they were being worked as late as the end of the round barrow period. The skeletal remains of two individuals, one male, one female, were discovered. These have been examined by Sir Arthur Keith and exhibit evidence of a first cross between round and long barrow peoples.

Mr. Pull's excavations have evidently been conducted with great skill and his results are described with full and constant reference to their bearing on broader issues. He has made a valuable contribution to the history of the flint-mining industry in Britain.

Middlesex in British, Roman and Saxon Times. By Sir Montagu Sharpe. Second edition, revised. Pp. xix + 240 + 5 plates. (London: Methuen and Co., Ltd., 1932.) 15*s.* net.

SIR MONTAGU SHARPE has made considerable additions to this new edition of his account of the archæology of Middlesex in the period extending from just before the Roman conquest down to Domesday, which was first published in 1919. It will be scarcely necessary to recall his vivid reconstruction of Middlesex life in the British period, the detailed treatment of matters affecting the land and settlement, or the intimate knowledge of county topography which was displayed in the discussion of communications, of the exact point at which Cæsar crossed the Thames, or of the scene of Boadicea's last battle.

The attention which was directed in the earlier edition to the Roman land survey and its relation to the ancient ways, has borne fruit and much fresh information is now incorporated. A much enlarged and revised chapter argues that the Roman land system with the decuria survived in Saxon times in the common field and the tything and is to be discerned in detail in the particulars of Domesday. Other additions or revisions are a new table giving with dates the earliest known form of the names of many places in the county, a diagram explaining the Roman method of distributing plots for cultivation in the common fields, and a map of the common fields in a Middlesex parish so late as 1813.

Modern Handbooks on Religion. By the Rev. A. C. Bouquet. (1) *A Study of the Ordinary Arguments for the Existence and Nature of God.* Pp. iii + 63. 2*s.* 6*d.* net. (2) *Religious Experience: its Nature, Types and Validity.* Pp. v + 133. 3*s.* net. (3) *Phases of the Christian Church: a Short View of its History.* Pp. v + 150. 4*s.* net. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1932.)

Too many vital problems are raised in these small handbooks on religion to dispose of them with a few casual remarks. The general aim of the author, however, deserves a strong support. He wishes to restate in the light of modern knowledge, the ordinary arguments for the existence and nature of God, the nature and types of religious experience and the interpretation of the development of Christianism. To Anglicans and non-Conformists in general, these books should be welcome, in so far as the rational and technical study of these questions has been allowed in recent years to fall into the background, partly on account of the emphasis which has come to be laid upon intuition and direct experience, partly because philosophical criticism has apparently weakened its validity and value. To Catholics, however, though some pronouncements and interpretations of the author will appear highly controversial, these studies will provide an alternative ground of reflection, the more so as they are put forward by a sincere Christian and a genuine scholar. T. G.

Drehung der Polarisationsebene des Lichtes. Von W. Kuhn und K. Freudenberg. (Hand- und Jahrbuch der chemischen Physik, herausgegeben von A. Eucken und K. L. Wolf, Band 8, Abschnitt 3.) Pp. ii + 142. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1932.) 12.80 gold marks.

THIS monograph is in four sections dealing with the asymmetric molecule, optical rotation and circular dichroism, physical explanations of optical rotatory power and optical rotation in relation to chemical constitution. It contains an excellent account of the work done by the authors in Heidelberg and Karlsruhe, and will be welcomed by those who wish to read it in a less costly medium than Freudenberg's "Stereochemie".

The Royal Entomological Society of London

On May 3, 1833, a few enthusiastic entomologists met in the rooms at the British Museum then occupied by Mr. J. G. Children, at that time an official of the Natural History Department, and resolved to establish a society for the promotion of the science of entomology in its various branches. This was the inauguration of the body which, under the designation of the Entomological Society of London, has just completed a hundred years of useful and increasingly beneficial activity.

Previous attempts had been made to form an association with the same or similar objects, the first of which attempts can be traced to a date at least so early as 1745, when an association, under the name of the Aurelian Society, is recorded to have held meetings at the Swan Tavern, Change Alley. This, however, and several other societies afterwards established with the like aims, had only an ephemeral existence; and it was reserved for the small company which met as stated on May 3, 1833, to found an organisation which, after passing through many vicissitudes and suffering many perils that seemed to threaten its very existence, has to-day reached a position of permanent security.

To this result many distinguished votaries of the science have, in their several ways, contributed. Among the original members of the Society was J. O. Westwood, to whom more than to any other person is due, as the present honorary secretary, Dr. S. A. Neave, says in the "History of the Entomological Society" which he has compiled with the assistance of the registrar, Mr. F. J. Griffin, and just published*, the successful growth of the enterprise during this early period. Westwood was unremitting in his efforts for its welfare; the influence which he exercised in various official positions, including three periods as president, was most valuable; and in the jubilee year, 1883, his services met with due recognition by his unanimous election as honorary life president.

Those who knew Westwood recall with affectionate appreciation his genial and kindly nature, tempered with a touch of oddity, and his old-fashioned outlook on many scientific questions, not entirely unprejudiced, but never bitter. His association with Hope, one of the original officers, led to his appointment as keeper of the collection and library presented by Hope to the University of Oxford, and ultimately to his occupancy of the Hope professorship of zoology founded in 1861.

The financial difficulties encountered by the Society in a critical period of its career might well have been fatal to its continued existence but for the generosity of J. W. Dunning, a fellow of Trinity College, Cambridge, whose gifts, many of them anonymous at the time but now known to be his, included the whole expense incurred in connexion with the grant of the Royal Charter in 1885 and cannot have fallen far short of £1,000.

In the list of those who have occupied the presidential chair are found the names of Sir John Lubbock, afterwards Lord Avebury, Lord Walsingham, F. Du C. Godman, R. Meldola, R. Trimen, N. C. Rothschild and Lord Rothschild. H. W. Bates was president in 1868–69, and was followed in 1870 by Alfred Russel Wallace, his associate in their famous journey to the Amazon. Bates again became president in 1878. Darwin was an original member, and was vice-president in 1838, but never filled the presidential chair.

Besides Westwood, the only other recipient of the honour of the life presidentship until the present occasion was the Rev. W. Kirby, joint author with W. Spence of the well-known "Introduction to Entomology". At the recent centenary celebration, Prof. E. B. Poulton, who succeeded Westwood as Hope professor at Oxford, was accorded the highest honour in the power of the Society to bestow, and became the third holder of the distinguished office of honorary life president. Prof. Poulton, who had held the presidentship on three separate occasions, was acknowledged by all to have advanced the cause of entomology in general and of the Society in particular more efficiently than any other living person. The introduction which he has furnished to the admirable "History" of the Society is a most interesting record of his memories of the Society over a period of fifty years, and includes some notable words both of warning and encouragement, the fruit of wide experience and ripe consideration. It was universally felt that he was, without any doubt, the right person to preside over the Society in this hundredth year of its existence, and his holding of the office is happily signalised by the Royal Command in accordance with which the Society has now the distinction of adding the word 'Royal' to its name.

It is interesting to note the various places in which, from time to time, the Society has found a home. The first general meeting after the founding of the Society in J. G. Children's quarters at the British Museum took place at the Thatched House Tavern, St. James's Street; but before the end of the year a fresh domicile was acquired at 17 Old Bond Street. Here the Society remained until 1852, when it removed to 12 Bedford Row. Some years after this, an arrangement was made by which the library was left at Bedford Row, but the meetings were held by the hospitality of the Linnean Society in the latter's rooms at Burlington House. In 1874 a proposal was set on foot for an amalgamation of the two Societies; but difficulties arose about the accommodation of the library, and the scheme fell through. In 1875 a home was found for the entomologists at 11 Chandos Street, quarters which they occupied as tenants of the Medical Society of London, until in 1920 the present house, 41 Queen's Gate, was bought and in the course of the next few years was gradually adapted for all the purposes of the Society.

---

* The History of the Entomological Society of London, 1833–1933. By Dr. S. A. Neave, assisted by F. J. Griffin. With an Introduction by Dr. E. B. Poulton, and a Financial Chapter by A. F. Hemming. Pp. xlvi+224+8 plates. (London: Entomological Society of London, 1933.) 10s. 6d.

That this solution of the housing difficulty became possible was due to the exertions and generosity of many of the Society's members, and especially to the untiring activity and skilful management of W. G. Sheldon as honorary treasurer. The house in its present condition must strike every visitor as being excellently fitted for its purpose. The library, which occupies the whole of the first floor, contains the extremely valuable collection of books belonging to the Society, well arranged in substantially constructed bookcases and adequately catalogued. There are a council room and commodious offices on the ground floor, but the chief glory of the house is the new lecture room, which has been built on the basement level at the back of the property. This is a remarkably handsome structure, well-proportioned and suitably furnished; but what gives it its main distinction is the oak-panelled interior and finely moulded ceiling, the latter a reproduction of the work in the Bromley Room at the Victoria and Albert Museum. These features, together with the presidential chair and desk, structures worthy of their surroundings, were provided by Mr. R. W. Lloyd, a fellow of the Society, entirely at his own expense.

On the walls of the rooms and staircase at Queen's Gate hangs an interesting collection of portraits of prominent fellows of the Society; and in one of the ground-floor rooms is a large painting by J. Cooke, "The Aurelians", depicting Dr. G. B. Longstaff, a keen and travelled entomologist and generous benefactor to the fund for the purchase of the Queen's Gate House; and his friend Selwyn Image, also an enthusiastic entomologist and sometime Slade professor of fine art in the University of Oxford.

The celebrations of the Society's centenary lately held were attended by a large number of delegates from the British Empire and from foreign countries. The proceedings included a general meeting on May 3, when speeches were made and addresses presented, a scientific conversazione at Queen's Gate, a reception by the trustees of the British Museum, a supper at the Gardens of the Zoological Society of London, excursions to Tring and to Whipsnade, and a reception by His Majesty's Government at Lancaster House. F. A. D.

'Red Coal'

MAN is unceasing in his quest for power—social, political and mechanical. In his search for sources of mechanical power, which, with a charming allegiance to the past, is still associated with the horse when it is measured, man has dug deep mines to bring 'black coal' to the surface and learned how to convert energy into steam and electricity. He has harnessed the waterfall—'white coal'—to the same end, making it swiftly turn a wheel, a turbine, and put areas containing only rivers on an equality with those perched on top of the coalfields. In one favoured district he has dared those forces of the inner earth which manifest themselves as volcanoes, or in their milder form as fumaroles, and tamed their steam to pass through turbines and generate electricity, which may be regarded as produced from 'red coal'.

The story of this achievement, largely that of Prince Ginori Conti and his devoted band of helpers, is a thrilling one: it has in part been told in these columns by him (NATURE, 121, 59, Jan. 14, 1928), and it has been brought up to date in a lecture delivered by him before the Royal Society of Arts on May 3.

Originally the enterprise was a chemical one to exploit the boric acid contained in the *lagoni* discovered by Höfer in 1777, and begun by Larderel in 1818; for fully fifty years, Tuscan boric acid was practically without a competitor in the world's markets. To-day the use of the steam to produce electricity is the important activity, and to-morrow it may well be that the amount of cheap power produced in this way will have a deciding effect on the progress of Italian industry.

Three factors have contributed to the advance: the gradual development under Prince Ginori Conti's leadership of a technique for steam drilling; the fact that the wells maintain a steady head of steam and are not intermittent like the geysers in Yellowstone National Park; and the development of turbines of the free exhaust type.

The rotary or percussion systems of drilling, or both alternatively, are used; for the *soffioni* steam is often found at a depth of 100 ft. and, as the jet increases in volume, drilling becomes more difficult. There comes a moment when the steam gains the upper hand and an explosion takes place with the expulsion of stones and mud and a deafening noise which goes on for weeks and can be heard for several miles. The biggest well, completed in 1931, has an output of 440,800 lb. of steam per hour at a pressure of 3·5 atmospheres with a temperature of 205° C. A second large well completed a year after has an hourly output of 396,000 lb. of steam.

The total output of steam from all the wells of the district is now estimated at more than two million lb. per hour. Only a portion is utilised for feeding the power plants; these are yielding continuously 12,000 kw. for which there is a regular demand. Now that confidence in the trustworthiness of the supply has been obtained, the amount of power generated may be expected to increase rapidly.

The volcanic region around Larderello has been but scantily explored so far; it is believed, however, that all the Tuscan *soffioni* have one common origin.

The choice of condenser or free exhaust turbines is an economic question involving careful study. The latter have advantages from the point of view of economy in installation, upkeep and running costs, but they also have a higher steam consumption.

There is little that is new in the production of boric acid at Larderello, which is putting on the market a crude acid of 95 per cent purity; this industry is to-day a highly competitive one consequent on the discovery of vast quantities of boric acid at Searles Lake, California, and elsewhere.

The steam contains about 6 per cent by weight of gas, of which about 92 per cent is carbon dioxide. A large plant has been erected for its separation and compression, both to liquid and solid carbon dioxide, both products which have increasing importance for refrigeration and other purposes.

Work is in hand also to separate the sulphur dioxide for the production of hyposulphites and sulphites, and further, the methane which, if obtained sufficiently cheaply, can be made the source from which to obtain numerous synthetic carbon derivatives. It is projected even to obtain the rare gases, including helium, which, it is believed, is present in sufficient proportions to justify its separation.

To those with vision, the whole achievement is a very remarkable one. The *soffioni* steam is being exploited in the most complete manner, both on account of its thermal and of its chemical value: to draw from the earth a source of power and at the same time obtain from it an antiseptic, a fertiliser, a refrigerant, a photographic chemical, an illuminating gas as well as the rare gases, makes the inferno a source of wealth far richer than Aladdin's Cave. The exploitation of such riches is a task which is taxing to the full the ingenuity and ability of Italian engineers and chemists, who are proving well fitted for their honourable task. There can be no more convincing example of a saying of Sir Oliver Lodge's which Prince Conti quoted: "There is lavishness in Nature but no waste."

The organisation under the leadership of Prince Conti has been built up as the result of full recognition of the vital importance of what pure or fundamental research can contribute towards the better utilisation of natural resources: it was also emphasised how completely it has enjoyed the support of the Italian National Government. Great have been the ravages wrought in Italy by volcanic disturbances; perhaps they may be to some extent equated in the future by the benefit arising out of the harnessing of their forces in the manner described.

Leicester Meeting of the British Association

FROM the point of view of the British Association, Leicester is a changed city since the meeting in 1907. When the Association meets there on September 6–13, a whole range of fine buildings will be found to have become available since 1907 for its use. The Wyggeston Girls' School, where the reception room, offices, and one of the sections will be established, must be one of the most notable buildings of its kind in the country. The University College, though it occupies an old building, was not established at the time of the last meeting: it now offers accommodation for sections and the inspiration which, for such an occasion as an Association meeting, is afforded by the mere existence of such an institution. The Wyggeston Boys' School adjoins it. The De Montfort Hall is admirably suited for the inaugural meeting. These and other available buildings have the advantage of being situated conveniently to the centre of the city but outside it, a consideration making for the comfort of audiences as external noise is avoided, and access is easy.

Among the many points of interest for scientific visitors in the area for which Leicester is the centre—and they are far more numerous than is realised, probably, by most people—Loughborough College must be specially mentioned. This institution, the outcome of engineering and kindred activities during the War, is of peculiar interest in itself. But not only this: it also offers, what Leicester itself does not, save for the purposes of the secretariat and a few other members, a remarkably fine series of hostels. Living accommodation in hostels during Association meetings is found always to be popular among visiting members, and those who like it need not be discouraged by the distance of thirteen miles from Leicester, for rail and road communications are easy and quick.

The preliminary programme just issued and obtainable from the Association offices at Burlington House, Piccadilly, London, W.1, gives details of the foregoing arrangements and much else besides. The city itself is seen to be well provided with hotels and private hotels convenient to the meeting-rooms. The list of possible excursions and visits indicates the wide scientific interests of the locality. Charnwood Forest, Derbyshire, the Fen Country, the Warwickshire area, are all within reach. Many industrial, agricultural, and educational establishments are to be seen, the last including University College, Nottingham.

The president, Sir Frederick Gowland Hopkins, combining for the year the onerous duties of the chairs of the Royal Society and of the Association, will deal in his inaugural address with the chemical aspects of life. As for the programme of scientific transactions at large, the Association cannot be accused of neglecting current affairs of public interest. The policy of tackling such topics as the gold standard and increasing the supply of gold, a national educational system, the evolution of terrestrial life, industrial physics, and others which find place in the present programme, has its rewards, and occasionally something more. The introduction of some pregnant subject of public concern has sometimes led people to ask why the Association does not do more than merely talk about them: a few were disappointed last year when one noteworthy pronouncement was not followed by immediate action; and quite lately a newspaper correspondent demanded that the Association should not merely formulate a remedy for unemployment, but also apply it. Such action may be scarcely within the Association's powers.

On the other hand, the effort indicated in the programme and by documents issued along with it, to bring the publications of the Association more widely into notice, is an effort, deserving of all support, toward the removal of a weakness. The Association, though supplying to the ephemeral press and to specialist publications a vast range of scientific material, has never yet itself become as effective a recording instrument as stronger public support might make of it.

The Association, from the point of view of those who must raise local funds for its reception, is a less exacting guest than it used to be, and it is right and indeed necessary that this should be so. The programme gives amply sufficient evidence of the hospitality which Leicester intends to offer, including as it does a reception to be given by the Lord Mayor (Councillor Arthur Hawkes), another by the Leicester Literary and Philosophical Society, and a garden party by the University College. Nor, as already suggested, will Leicester fail in the heavy task of finding meeting-rooms—for in that matter the Association does not moderate its demands. Yet, when sections ask to form departments and run two or three meetings at once, or propose to arrange cinematograph or other demonstrations, it would be ungenerous to deny opportunities to the devoted bands of workers who arrange the sectional programmes for the honour of science and the Association, and maintain, as in the present programme they certainly do maintain, the high standard of interest which they and their predecessors have set up. Participation in the Leicester meeting may be confidently recommended, for the sake not only of the Association, but also of Leicester.

Obituary

PROF. W. C. UNWIN, F.R.S.

TO understand the great debt which engineering science owes to the late Prof. William Cawthorne Unwin, it must be remembered that it was in 1856 that he started on his engineering career and that it is sixty-five years since he first began to teach engineering. Born at Coggeshall in Essex, on December 12, 1838, Unwin had all the advantages of being brought up in academic surroundings, for his father, Dr. William J. Unwin, was principal of Homerton College.

On leaving school in 1856, Unwin was fortunate in being apprenticed to Sir William Fairbairn, an engineer and a most distinguished research worker in engineering science. As might be expected in those early days of experimental engineering, the work was of a most varied nature and this had an important bearing on Unwin's later work. Elaborate researches were carried out on the specific volume of saturated steam, and on the effects of repeated loading of plate girders, the most arduous part of the experimental work devolving on the young and enthusiastic Unwin. But, though interesting and instructive, engineering research was not very remunerative and, no doubt, Unwin was recalling his own experiences when in one of his latest addresses, he deplored the fact that the importance of engineering research was not even then recognised by those who had charge of great engineering undertakings. Working at engineering research all day Unwin found time at night to continue his studies, and in 1860 took the degree of B.Sc. at the University of London, where he played so important a part many years later when the course for a degree in engineering was being arranged.

In 1862, theoretical and practical training completed, Unwin became manager at the works of Messrs. Williams at Kendal where the manufacture of Thomson's new vortex turbine had been begun. Then, in 1867, he was appointed manager of the engine department of the Fairbairn Engineering Company. He remained, however, only a short time with this firm, as in 1868 he was made instructor in marine engineering in the Royal School of Naval Architecture, and in 1872 he was appointed professor of hydraulics and mechanical engineering at the Royal Indian Engineering College, Coopers Hill, which position he held until 1884. In 1877 was published his textbook on the "Elements of Machine Design", probably the most widely known of all his books and deservedly so. He wrote as a teacher who gave his readers the necessary information acquired either by his own research or by that of others. Clear and concise explanation was his strong point, and so no textbooks are required to explain Unwin.

Unwin's great success as the teacher of young engineers became possible when in 1884 he was appointed professor of civil and mechanical engineering in the newly established City and Guilds Central Technical College. London was at last to have a college in which engineering science could be taught systematically, in suitable laboratories, equipped with all the necessary plant and apparatus. Four departments were established—chemistry, engineering, mathematics and physics—presided over by Armstrong, Unwin, Henrici and Ayrton respectively, all experts in their subjects and all experienced and enthusiastic teachers. From its very initiation the College was a success, and as a school of engineering an unparalleled success. Unwin's engineering students, trained in specially arranged courses in mathematics, chemistry, and physics, were able generally to profit fully from the instruction given by their exceptional teacher and though, at first, employers did not realise the importance of having trained engineering assistants, still in time Unwin had the gratification of seeing his former students holding the highest positions in the engineering profession and in industry.

Unwin knew that to teach engineering one must practise it, and owing to his international reputation, he had no lack of consultation work. In 1890 an American company appointed an international commission of five eminent experts under the presidency of Lord Kelvin (then Sir William Thomson) to determine the best way of developing the power at Niagara and distributing it. The headquarters of the Commission were at the 'Central' and Unwin was the secretary. In his report he discussed fourteen different proposals which were presented and none of which was considered suitable. He continued to serve on the Commission, making several trips to Niagara to study the conditions of the problem on the ground and advising in connexion with the actual project. He also carried out a long research on the flow of tidal waters in the Thames with reference specially to the pollution of the upper waters by the sewage from the London main outfalls. He was consulted with regard to the Coolgardie Hydraulic Scheme and prepared a report on the loss of head in the mains of the proposed South Staffordshire power gas scheme.

Recognised now as the leading expert in engineering education, Unwin was practically the author of the course in engineering for the London degree and so naturally the course laid down was the same as that followed at the 'Central'. When later the 'Central' became the engineering section of the Imperial College of Science and Technology, Unwin often stated that one of the chief advantages to the University would be the possibility of having many alternative subjects for the degree—a possibility of which advantage has been taken in later years, certain courses given at different schools of the University being recognised as equivalents, allowing in this way a much wider choice to the student.

In 1904 Unwin resigned his professorship, being appointed professor emeritus, but he by no means gave up his engineering practice. His close touch with the profession was maintained. On the council of the Institution of Civil Engineers he had a large part in framing the new proposals relating to the preliminary training of the civil engineer, and when in 1911 he was elected president of the Institution, his presidential address discussed specially the training of the young engineer. In 1915 he was elected president of the Institution of Mechanical Engineers, and again in 1916.

It is usual in this generation to speak of a man's War service, and certainly mention of Unwin's must not be omitted. At the age of seventy-seven he devoted his technical knowledge and business ability to his country and served on the Management Board of the Metropolitan Munitions Committee from 1915 until 1918.

Unwin was a great teacher. While not a brilliant lecturer he was always sound and was valued by those looking for reliable up-to-date information expressed in the clearest language. That his lectures outside the class-room were highly appreciated may be judged by the number of special lectures he was asked to give: the Cantor lectures, the Howard lectures, the James Forrest and James Watt lectures. In the class-room his lectures were definitely serious. In an engineering college in which there is only a qualifying entrance examination there must be many students who are not likely to go very far in the profession, but all those who attended Unwin's lectures remember him with affection. He was not one to suffer fools gladly, but he was very willing to help the real student. He did not wander in the least from the subject in hand, and he had his own methods for gauging his students' capacity. In later years they were often surprised to know how much the professor knew of the personality of each of his students. He had a keen sense of humour, but he probably appreciated his own jokes more than those of other people.

Unwin's long life, though filled with interest, was uneventful. He did not marry. While a most genial companion, he would not talk of himself, and his correspondence was only professional. His published papers, reports and textbooks range into all fields of engineering so that his working hours were fully occupied. But he did take vacations, though his recreations were tranquil and scientific. He was an enthusiastic fisherman and devoted many hours to photography, having begun as an amateur in the early days of the wet plate, and on all his travels a camera went with him. Though he had travelled considerably he was no wanderer, and it is typical of him that he lived the last fifty years of his life in the same house where, since his retirement from the 'Central', his niece, Miss Dorothy Unwin, was his devoted companion. He died on March 17. Few men who have lived to so great an age have left so many who are glad to have known them.

Naturally many distinctions were conferred on him. He was awarded the Kelvin medal, was a fellow of the Royal Society, LL.D. of Edinburgh, honorary member of both the American Societies of Civil Engineers and Mechanical Engineers and an honorary associate of the Royal Institute of British Architects.

S. M. D.

News and Views

Sir John Marshall, C.I.E.

SIR JOHN H. MARSHALL, it is reported by the Bombay correspondent of the *Times*, has been awarded the triennial gold medal for historical research by the Royal Asiatic Society of Bombay. Sir John Marshall, who was director-general of the Archæological Survey of India from 1902 until 1931, was formerly a scholar of King's College, Cambridge, and was a student of the British School of Archæology at Athens in 1898–99. He was Prendergast student in 1900–1 and Craven student in 1901–2, while in 1927 his old college made him an honorary fellow. Under his directorship, the work of the Archæological Survey of India has been much stimulated, especially in the direction of excavation of prehistoric and early historic sites. It was due to him that the work was undertaken which led to the epoch-making discovery of the prehistoric sites in the Indus Valley at Harappa and Mohenjo-daro, and on his initiative that the co-operation of investigators from outside the service, experienced in the exploration of the sites of Mesopotamia and with knowledge of the cultures of that area, was invited.

Prof. Paul A. Murphy

THE Royal Dublin Society's Boyle medal, awarded to Prof. Paul A. Murphy in recognition of the value of his work in phytopathology, was presented to him at a special scientific meeting of the Society on May 5. The medal, which was instituted in commemoration of Robert Boyle, the illustrious Irish chemist, is awarded to Irish workers in all branches of science, pure and applied, whose work is adjudged to be of outstanding merit and importance. It was first awarded in 1899 to Prof. G. Johnstone Stoney for his work, which included what was probably the first approximate estimate of the electronic charge. Prof. Murphy's name is the eleventh on the list of holders. In presenting the report of the Committee of Science recommending the award of the medal, Prof. H. H. Dixon gave a brief summary of Prof. Murphy's work, which may be said to have commenced with his investigations in conjunction with Dr. G. H. Pethybridge into the life-history and biology of *Phytophthora infestans*, the fungus responsible for potato blight. Prof. Murphy then attacked the problem of the virus diseases and showed that the progressive deterioration which generally occurs in every variety of the potato is attributable to the accumulation of virus in successive crops. His work has also thrown much light on the complex nature of many virus diseases. He has contributed largely to our knowledge of various diseases of other plants, amongst which onion mildew and dry rot in turnips may be especially mentioned. Sir Frederick Moore, in supporting the award, referred especially to the great value of the work on potato blight, and of the important bearing of the investigations into the virus diseases on the seed potato industry. In making the presentation to Prof. Murphy, the Right Hon. Viscount Powerscourt, president of the Society, pointed out how particularly appropriate it was for the presentation to be made at a meeting held during the Society's Agricultural Show, since Prof. Murphy's work, in addition to being of great importance to pure science, is also a very valuable contribution to the advancement of agriculture, thus linking the two great branches of the Society's activities.

International Colonial Conference, 1935

A BRIEF announcement in the latter part of last month that Lord Lugard had been elected president of the Institut Colonial International at the biennial conference held at Lisbon on April 18–20 seems to have attracted very little attention. In an article by Prof. Basil Williams which appears in the *Times* of May 4, it is pointed out that Great Britain, the power most extensively interested in questions relating to colonial administration, has taken a relatively unimportant part in the conferences held by the Institut. These have been supported more especially by France, Holland, Belgium and Portugal. Great Britain, the United States and Italy, however, as well as these powers, are represented in the secretariat of the Institut. As the next conference will be held in London in 1935, under the presidency of Lord Lugard, and among the subjects already marked for special consideration is the question of the detribalisation of natives, it may be hoped that an active part will be taken in the work of the conference by officials and others who are concerned, whether in practice or as a matter of scientific study, with the administration of native affairs. A conference in London should afford an especially favourable opportunity, such as will not recur for some time to come, of pooling the views and experience of an exceptionally large and well-informed membership on the causes and effects of detribalisation, and, should opinion incline to the view that it is inevitable in the long run, of the best means of controlling and guiding it in the interests of the native. It is, perhaps, too much to hope for any approach towards a native policy common to all the powers and based on a thorough scientific study of the native, which would have any prospect of adoption by the countries represented at the conference.

Indian Rhinoceros at the London Zoo

FELLOWS of the Zoological Society, and the public at large, are greatly indebted to the King, who is the patron of the Society, for the young rhinoceros from Nepal which he has just given for permanent exhibition. It was presented to His Majesty by Maharajah Sir Judha Shumshere Jung, Prime Minister and Commander-in-chief of Nepal. Though the Society has two African rhinoceroses, it has only one Indian, which was presented by the Maharajah of Nepal nearly ten years ago; and since this animal is now found only in Nepal, where it is in sore need of protection if it is to escape speedy extermination, the recent gift is a valuable one. It will be interesting to compare the new arrival, which is 1½–2 years old, not only with the fully adult animal, but also with the African species, because of the striking and singular differences displayed by the two species in the matter of what one might almost call the 'armour-plating' formed by the hide. No one has yet been able to find any explanation for the fact that in the Indian species this forms what looks like a series of separate shields, or 'bucklers', studded with relatively small round bosses, while in the African species the hide forms a continuous covering. Again, we seek in vain for any intelligible explanation of the fact that while the African species has two nasal horns, in the Indian and other Asiatic rhinoceroses there is but one horn. There are, of course, other structural differences between these two types, which, some day, may be compared with all the known fossil remains. When this has been done, we may well find clues such as will help us to gain an insight as to the factors and mode of evolution of these singularly interesting ungulates.

The Old Ashmolean, Oxford

THE two hundred and fiftieth anniversary of the opening of the Old Ashmolean, Oxford, falls on May 21, a date duly recorded by Elias Ashmole, donor of its original possessions. In recognition of this occasion, Dr. R. T. Gunther, curator of the Lewis Evans Collection of Scientific Instruments, housed in the Old Ashmolean, has been able to conclude a series of arrangements to mark the event. Here it may be mentioned that the Old Ashmolean building itself was erected between 1679 and 1683, and is attributed, on fairly good grounds, to Christopher Wren. The appropriateness of this historic establishment for the housing of the Lewis Evans collection of ancient scientific instruments was demonstrated in 1925, when this notable gift to Oxford was dedicated by the Earl of Crawford and Balcarres at a special meeting held in the Old Ashmolean, and the collection was declared open. The principal celebration arrangements referred to above comprise a reception by the curator of the Lewis Evans Collection, on Sunday, May 21, whilst on May 22, at 2.30 p.m., in the University Museum, Sir Arthur Smith Woodward will deliver a lecture on "Plot and Lhwyd and the Dawn of Geology". These naturalists were the first keepers of the Old Ashmolean. During the week, exhibitions of Ashmolean interest will be open to the public, including portraits and relics, books, manuscripts, and engravings.

Centenary of the University of Zurich

THE centenary celebrations of the University of Zurich, which extended from April 28 until May 1, attracted a large number of delegates from the universities and learned societies of the world. At the chief ceremony, held in the noble 'Lichthof' of the University on April 29, the addresses of the Rector (Prof. F. Fleiner) and the director of education of Canton Zurich (Dr. O. Wettstein) were followed by congratulatory speeches by selected representatives of the various nations. The delegates from the British Isles were Prof. A. E. Zimmern (Oxford), Prof. G. H. F. Nuttall (Cambridge), Dr. T. Loveday (Bristol), Sir Henry Miers (Royal Society), Prof. J. Read (St. Andrews), Prof. E. Dieth (Aberdeen), Prof. J. H. S. Burleigh (Edinburgh), and Prof. F. E. Hackett (Dublin). At its foundation, the teaching staff of the University comprised twenty-three professors, thirty-three lecturers, and 161 students; at the present day, it has about a hundred professors, ninety lecturers, and some 2,000 matriculated students. In 1908, the University took a great step forward as a result of a referendum in which the people of Canton Zurich voted in favour of the provision of extensive new accommodation: "durch den Willen des Volkes", runs the inscription carved in stone over the western entrance to the magnificent central building which was erected at that time. The city of Zurich was *en fête* during the celebrations, and the popular interest and pride in the cantonal university were pleasingly evident on every hand. "Akademische Lehr- und Lernfreiheit ist an ihr geltend", is a significant sentence occurring in the original statutes of the University, and the adherence of the University, the canton, and the Swiss nation to the cherished ideals of freedom and toleration formed the keynote of most of the speeches at the celebrations.

Huxley and Scientific Education

HUXLEY memorial lectures have been delivered at the Imperial College of Science and Technology, London, annually since 1925 to commemorate the life and work of Thomas Henry Huxley, who was born on May 4, 1825, was professor of biology from 1854, and dean of the Royal College (then Normal School) of Science and Royal School of Mines from 1881 until his death in 1895. The lecture this year was delivered by Prof. H. E. Armstrong, who, as a pupil of Huxley's, and as professor of chemistry at the Central Technical College, and equally concerned with the outlook and methods of education, was able to garnish his tribute with personal reminiscence and with forceful criticism of the scientific world as it appears to him to-day. Huxley's reputation as a master of education rests, he said, mainly upon his writings and public addresses, not upon his work as a teacher. "He was a marvellous exponent—therefore, a bad teacher, as are all who are eloquent"; "a master of fine logic, but encased in hard bones". Prof. Armstrong attended some of Huxley's lectures, but they failed to hold the interest of one who hoped to learn how things had been found out; nevertheless, he ever regretted that he did not attend the Working Men's Lectures, in which Huxley told a consecutive story.

PROF. ARMSTRONG said he knew no book from which more general inspiration is to be derived than from the third volume of Huxley's essays, "Science and Education", though it was published in 1895 and goes back to 1854; yet there is little in the essays bearing on actual teaching. Huxley was insistent on the need for organisation. "In the sense in which he meant it, we remain unorganised to-day, whilst the need is much greater. Many may think that his

'Essays' are now out of date, that we have introduced Science into the schools and got what he asked for. It is not so. In fact, we have only the shadow—not the substance. The teaching, for the most part, is of the kind he abhorred and knew to be useless." "Huxley was undoubtedly a man of very great innate ability, a man who had gained full grasp of the world; he saw very clearly what the needs were, but was no master of method. Cannot men be found to study his great example but go further, especially in developing methods?" Prof. Armstrong said that it is in connexion with medical education that Huxley's instructions have been least regarded. Huxley complained specifically of the unsatisfactory character of the teaching in physiology and asked for a proper scientific foundation at school, followed by a minimum burden during the period of professional training.

Huxley's efforts to secure public recognition of the value of scientific education, said Prof. Armstrong, led to the establishment of the City and Guilds of London Institute for the Advancement of Technical Education and of its two colleges, the Finsbury Technical College (1879) and the Central Technical College (1884). The latter is now known as the City and Guilds (Engineering) College, and forms part of the Imperial College of Science and Technology. In an address on "Science and Culture", Huxley defended the thesis that for the purpose of attaining real culture an exclusively scientific education is at least as effectual as an exclusively literary education—to which Prof. Armstrong replies that he does not believe that either in itself can give us culture or is, in fact, possible exclusively. "The world insists on teaching a good deal, however much the schools may fail to teach." But Huxley made an important recommendation: that provision should be made for teaching sociology. Already in 1887 he foresaw the coming gravity of our industrial position, and wrote a remarkable letter to the *Times*. He called upon the nation to 'organise victory', and Prof. Armstrong echoed his words. A nation of shopkeepers, we have, he says, worshipped technical education; unfortunately, it has not taught us to keep shop: only to make things to be sold but not how to sell them, to the general good, when made. The problem of food looms in full face of a present need; that our food supply must be our first care is as yet realised by few. We can no longer allow uncontrolled use of the soil. We must learn how to use our knowledge. Scientific workers must bestir themselves to educate the public, even as Prof. Armstrong educates while he castigates.

New Medals of the Royal Aeronautical Society

Two new medals have been founded by the Royal Aeronautical Society, to be known as the British Gold Medal for Aeronautics and the British Silver Medal for Aeronautics. These medals have been founded following a request from Lord Amulree, when Secretary of State for Air, that the Royal Aeronautical Society should give some award for outstanding feats in aviation. A permanent Committee has been appointed to consider the awards of the medals, consisting of six members of the Royal Aeronautical Society, and the chairmen of the Royal Aero Club and the Air League of the British Empire. The design of the Gold Medal incorporates a portrait of Sir George Cayley and his first model aeroplane of 1804, and the design of the Silver Medal incorporates the Henson and Stringfellow machines. The medals will be awarded for an achievement leading to advancement in aeronautical science and will be confined, so far as possible, to subjects of the British Empire, but other nationals will not be excluded. The expenses of founding these two medals have been defrayed by the president, Mr. C. R. Fairey. The first awards of the British Silver Medal for Aeronautics have been made for the following achievements which have led to advances in aeronautical science: Capt. C. F. Uwins, for reaching a world record height in a heavier-than-air craft of 43,976 ft. on September 16, 1932; Squadron Leader O. R. Gayford, and Flight-Lieut. G. E. Nicholetts, who flew from Cranwell, England, to Walvis Bay, South Africa, non-stop on February 6–8, 1933, a distance of 5,340 miles.

Excavations in Northern Mesopotamia

Expectation of the importance of the results likely to be obtained by the joint expedition of the British Museum and the British School of Archæology in Iraq to Tell Arpachiyah in northern Mesopotamia under Mr. M. E. L. Mallowan is fully confirmed by the report of the first half season's work which appears in the *Times* of May 5. The expedition left London in January. It will be remembered that this site was selected for excavation as the result of a preliminary reconnaissance from Nineveh in the previous year. Surface finds of painted potsherds then suggested that this site would probably prove of great importance to the little-known earlier prehistory of northern Mesopotamia. The discovery of pottery of the Ur and Tell el-Ubaid type in mud-brick dwellings of a humble character on the top of the mound carries the first settlement well back into the fifth millennium B.C., and proves the site to be among the oldest yet discovered in Mesopotamia. As excavation proceeds, Arpachiyah is shown to be the centre of convergence for peoples transitional between neolithic and chalcolithic times; while connexions are being traced with Anatolia, Syria, southern Mesopotamia and, through Persia, with Baluchistan. It may be noted, in passing, that Arpachiyah supports and extends the evidence obtained by the American School of Oriental Research at Tepe Gawra and Tell Billa that northern Mesopotamia was a place of settlement for peoples from the north and north-east, who were there subjected to strong cultural influences from the south. Among the more noteworthy discoveries now reported at Arpachiyah are a method of fractional burial which is compared with the practice on the prehistoric site of Nál in Baluchistan, the use of a bucranium or ox's head as a motif to an extent which suggests a special cult, female figurines pointing to affinities with the Anatolian mother-goddess, a variety of beads and amulets, and a store of wheat, the earliest probably in Mesopotamia. Excavations are being carried through the lower levels in the hope of reaching virgin soil.

Road Research Station, Harmondsworth

In accordance with a recommendation of the Select Committee on Estimates of the House of Commons in its Second Report for 1932, arrangements have been made for the Road Research Station at Harmondsworth to be transferred from the Ministry of Transport to the Department of Scientific and Industrial Research as from April 1 last. The Committee of the Privy Council for Scientific and Industrial Research has decided to appoint a Road Research Board to advise generally on the conduct of road research undertaken by the Department, and with the concurrence of the Ministry of Transport, has appointed Major F. C. Cook, deputy chief engineer, Roads Department, Ministry of Transport, to be the first chairman of the Board. The following gentlemen have accepted invitations to serve on the Board :—Prof. R. G. H. Clements, Mr. T. Pierson Frank, Mr. W. J. Hadfield, Mr. W. P. Robinson, Prof. C. G. Cullis, Mr. E. V. Evans, Prof. E. H. Lamb, Prof. C. H. Lees, Lieut.-Col. Mervyn O'Gorman, and Dr. T. Franklin Sibly. The immediate direction and control of road research undertaken by the Department of Scientific and Industrial Research will be in the hands of Dr. R. E. Stradling, director of building research under the Department. Road tests throughout Great Britain under normal traffic conditions will continue, as heretofore, to be carried out by the Ministry of Transport in conjunction with the responsible highway authorities. In connexion with these tests, as well as the research work at the laboratory, and the issue of reports thereon, arrangements have been made for the closest collaboration between the Ministry of Transport and the Department of Scientific and Industrial Research.

Science Teaching

In connexion with the notice of Badcock and Holmyard's "Electricity and Magnetism for Beginners" in Nature of March 11, Dr. Dorothy Turner protests against the suggestion that a good qualitative treatment may involve the danger of dulling the pupils' subsequent interest in the subject when the time comes for more complete quantitative treatment, on the ground that for ninety-five per cent of those attending State-aided secondary schools such a time never comes. We referred Dr. Turner's letter to the reviewer who, however, still maintains that the essential danger to which teachers of science will have to give serious consideration is that, in the otherwise laudable desire to extend the ground covered, anything worthy to be called a training in science may be superseded by just talking about science, with the consequence that the subject may become little more than a branch of English, providing good topics for general knowledge essays.

Rockefeller Gift to the Royal Institution

It was announced by the Managers of the Royal Institution at the general monthly meeting of the members, held on May 8, that the capital payment of £20,000 promised by the Rockefeller Foundation nearly three years ago, on condition of obtaining £50,000 from other sources, had now been received. The gift was promised for the endowment of research in the Davy Faraday Research Laboratory of the Royal Institution, and the fulfilment of the Rockefeller promise implies that in the past three years the Managers have been successful in securing research endowment for the Laboratory to a total capital value of upwards of £70,000.

Spurious University Degrees

A Bill to prohibit the unauthorised use and issue of university degrees, a subject which has been taken up by the Association of Scientific Workers, was introduced into the House of Lords by Lord Jessel on May 3 and read a first time. The main part of the Bill, which, if passed, will be known as the University Spurious Degrees (Prohibition of Use and Issue) Act, proposes to make it a penal offence for any person to use letters after his name denoting a university degree unless he actually holds such a degree ; and also it prohibits the conferment of degrees by any person or organisation other than a recognised university. The term "recognised university" is defined at length ; briefly, it may be described as a university or similar institution granting academic degrees as a result of a prescribed course of at least three years' training or definitely recognised as a university by the government of the country where it is situated. The "Lambeth degrees" conferred by the Archbishop of Canterbury are definitely exempted from the provisions of the Act.

Californian Earthquake of March 10

This earthquake has been studied by Messrs. H. O. Wood and C. F. Richter, seismologists of the Pasadena Seismological Laboratory, and a summary of their results appears in the Mail Report of Science Service, Washington, D.C. for April 19. The intensity of the shock was far less than that of the Nevada earthquake of November 20–21, and may have been less than that of the Santa Barbara earthquake of June 29, 1925. The greater loss of life (about 120 persons) and property caused by the recent shock is attributed to the strongly shaken area being more thickly settled. In some places, considerable destruction occurred and this was probably due to the water-soaked alluvial nature of the ground ; but, in all, serious damage was confined to bad or improperly designed construction. The study of the records of seven seismographs in California under the charge of the Pasadena Laboratory shows that the origin of the earthquake was probably in one of a system of faults that runs parallel to the coast in the district between Huntington Beach and Newport Beach. The depth of the focus seems to have been less than usual and was probably about six miles. Nearly continuous movements were recorded for many hours afterwards, but none of the after-shocks was comparable with the main earthquake.

Announcements

THE first conversazione this year of the Royal Society will be held in the rooms of the Society at Burlington House, London, W.1, on May 17, at 8.30 p.m.

PROF. HENRY E. ARMSTRONG will deliver the sixth Hugo Müller lecture before the Chemical Society, in the meeting hall of the Institution of Mechanical Engineers, on May 25, at 5.30. The title of the lecture will be "Chemistry at the Cross Roads".

MR. H. BRADLEY will deliver the nineteenth "Physics in Industry" lecture before the Institute of Physics at the Royal Institution, 21 Albemarle Street, W.1, on May 23 at 5.15 p.m. The title of the lecture will be "Physics in the Boot and Shoe Industry".

THE Halley lecture for 1933 of the University of Oxford will be delivered in the lecture theatre at the University Museum on June 1, at 5 p.m., by Prof. Henry Norris Russell, professor of astronomy and director of the Observatory, Princeton University. The subject will be "The Composition of the Stars".

AT the ordinary meeting of the Royal Society of Edinburgh, held on May 1, the James Scott Prize for 1933 for an essay or lecture on the fundamental concepts of natural philosophy, was presented to Prof. Arnold Sommerfeld, professor of natural philosophy in the University of Munich. Prof. Sommerfeld, whose lecture was entitled "Ways to the Knowledge of Nature", dealt with a recent book of similar title by Prof. Max Planck, and gave his own views on such questions as the mathematical character of the laws of Nature, causality, duality in physics and in human life.

AT the anniversary meeting of the Royal Society of South Africa, held on March 15, the following officers for the year 1933 were elected :—*President :* Dr. A. W. Rogers ; *Hon. Treasurer :* Prof. L. Crawford ; *Hon. General Secretary :* Dr. B. F. J. Schonland.

MR. H. T. PAGDEN, assistant entomologist in the Agricultural Department, Straits Settlements, has been appointed by the Secretary of State for the Colonies to be entomologist in the British Solomon Islands Protectorate.

IN our issue of April 29, p. 612, reference was made to resignations of Jewish professors from university chairs in Germany. During the past few days, the following three distinguished chemists have resigned their posts : Prof. F. Haber, director of the Kaiser Wilhelm Institut für physikalische Chemie und Elektrochemie, Berlin-Dahlem, who was awarded the Rumford medal for 1932 of the Royal Society for his work on physical chemistry, notably in the application of thermodynamics to chemical reactions ; Prof. H. Freundlich, author of works on colloid chemistry, and Prof. M. Polanyi, distinguished for his work on physical chemistry, both of whom were also at the Kaiser Wilhelm Institut.

THE Society for Cultural Relations between the Peoples of the British Commonwealth and the U.S.S.R. is organising tours of medical men and scientific workers to the U.S.S.R., and the first party will leave London for Leningrad on July 1. The return journey will cost £22–£36 inclusive, according to the type of accommodation selected. The party will spend a total of sixteen days in Russia ; three days in Leningrad, five days in Moscow, then either (*a*) Gorky, down the Volga to Stalingrad—Leningrad ; (*b*) Rostov/Don, Kharkov—Leningrad ; or (*c*) Kharkov, Kiev—Leningrad. The latest date for receiving applications for the first party leaving London is June 15. Inquiries should be addressed to the Secretary of the S.C.R., 1 Montague Street, London, W.C.1.

ON May 23, the second part of a two volume work entitled "An Introduction to the Sociology of Islam", by Mr. Reuben Levy, lecturer in Persian at the University of Cambridge, will be published by Messrs. Williams and Norgate, Ltd., for the trustees of Herbert Spencer, in continuance of his "Descriptive Sociology".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :—A technical assistant to the Adviser in Agricultural Economics at Armstrong College, Newcastle-upon-Tyne—The Registrar (May 16). A full-time lecturer in chemistry at the Wigan and District Mining and Technical College—The Principal (May 19). A junior assistant bacteriologist and demonstrator at the University of Sheffield—The Registrar (May 20). A Sharpey physiological scholar at University College, London—The Secretary (May 27). A principal at St. Katherine's Training College for Women Teachers, Tottenham—The Rev. Canon G. L. Gosling, S.P.C.K. House, Northumberland Avenue, W.C.2 (May 31). A lecturer in mathematics at East London College, Mile End Road, E.1—The Registrar (May 31). A head of the Department of Electrical Engineering and a lecturer in the Department of Mechanical Engineering of the Central Technical College, Birmingham—The Principal (June 3). A lecturer in organic chemistry at the Manchester Municipal College of Technology—The Principal (June 14). A University lecturer and a University demonstrator in physics—The Secretary, Appointments Committee of the Faculty of Physics and Chemistry, Clare College, Cambridge. A mechanical engineer in the Egyptian Irrigation Service in the Sudan—Chief Inspecting Engineer, Egyptian Government, 41, Tothill Street, S.W.1. A full-time assistant in the Engineering Department of the Technical College, West Hartlepool—The Secretary, Education Offices, Park Road, West Hartlepool. A plant engineer for the locomotive, carriage and waggon shops of the South Indian Railway Co.—Messrs. Robert White and Partners, 3, Victoria Street, London, S.W.1.

Boric Acid in Sea Water and its Effect on the Carbon Dioxide Equilibrium

ACCORDING to recent investigations on the boron content of sea water, amongst others, spectrographic analyses by V. M. Goldschmidt and Cl. Peters[1], the boron content is considerably higher than hitherto assumed. In consequence, quantitative analyses for this substance have been undertaken in several laboratories. The following table shows the results of a series of titration analyses of five different water samples of varying salinity, giving the origin of the sample, the boric acid content in milli-equivalents per litre and in grams B_2O_3 per cub. m., as well as the chlorinities in per mille and the ratio boron to chlorine.

Origin	Latitude	Longitude	$Cl^{\circ}/_{\circ\circ}$	Boron content		Ratio $B^{\circ}/_{\circ\circ}/Cl^{\circ}/_{\circ\circ}$
				m. equ./l.	B_2O_3 gm/m.^{3}	
English Channel, Plymouth	—	—	19·33	0·456	15·9	0·000248
North Sea	55°39′ N	4°50′ E	19·20	0·433	15·1	0·000237
Cattegat	57°35′	11°08′	13·32	0·292	10·8	0·000233
Cattegat	56°16′	12°25′	6·89	0·157	5·8	0·000242
North Baltic	59°30′	22°35′	3·41	0·078	2·7	0·000245

Oceanic water thus contains 15 gm. B_2O_3 per cubic metre as against 0·7 as given in oceanographical textbooks. The values for the ratio boron to chlorine agree well with the results (received by private communication) by H. W. Wattenberg, Institut für Meereskunde, Berlin, who found the value $0{\cdot}250 \times 10^{-3}$, and by E. G. Moberg and D. M. Greenberg, Scripps Institution, La Jolla, California, whose values vary between $0{\cdot}235 \times 10^{-3}$ and $0{\cdot}242 \times 10^{-3}$.

As the presence of boric acid may affect the carbon dioxide equilibrium of sea water, recently investigated by a committee of the International Council[2], it was desirable to repeat the determinations of the second dissociation constant of carbonic acid in *boron-free artificial* sea water. The constant determined by the Committee is a working constant, valid in a certain pH range. The new determinations of K'_2 were carried out at 20°, with artificial sea water of varying salinity. The result may be summarised in the following equation relating the negative logarithm of the constant, pK'_2, to the chlorinity of the water:

$$pK'_2 = 10{\cdot}45 - 0{\cdot}682\sqrt[3]{Cl^{\circ}/_{\circ\circ}} + 0{\cdot}020Cl^{\circ}/_{\circ\circ}.$$

For 35 per mille sea water, the value of pK'_2 is 9·00. By means of this constant and determinations of boric acid and total carbon dioxide, it is possible to calculate also the apparent dissociation constant of boric acid in sea water at different salinities. The following relation was found between the negative logarithm of the constant pK'_B and the chlorinity:

$$pK'_B = 9{\cdot}22 - 0{\cdot}123\sqrt[3]{Cl^{\circ}/_{\circ\circ}} - 0{\cdot}0086Cl^{\circ}/_{\circ\circ}.$$

For water of 35 per mille the value of pK'_B is 8·72. Calculation of the different carbonic acid constituents of sea water is possible when chlorinity, pH and alkali reserve are known. The values of total carbon dioxide as given in the tables worked out by the Committee of the International Council are at the most 2·5 per cent lower than those obtained when both pK' and the corrected pK'_2-value enter into the calculations. The tension of carbon dioxide is not appreciably affected by the boric acid.

Calcium Isotope with Mass 41 and the Radioactive Half-Period of Potassium

CAREFUL determinations have been made of the atomic weight of calcium extracted from two very old potassium-rich deposits—one a felspar from Rhiconich, Sutherlandshire, estimated at 1,000 million years old, the other a pegmatite from Portsoy, Banffshire, probably about 600 million years old. Each mineral contained approximately 9 per cent K_2O and less than 0·3 per cent CaO, so that there seemed reasonable grounds for hope that the accumulation of the calcium isotope with mass 41, through the slow radioactive disintegration of the potassium in the deposit, might be sufficient to induce a detectable change in the atomic weight from the normal value.

Extraction with hydrochloric acid removed about one-third of its calcium content from the finely pulverised rock very rapidly. The residue proved much more resistant and, in view of the probability that 'abnormal' calcium atoms, occupying the position of their parent potassium in the crystal lattice, were being preferentially extracted, no attempt was made to carry the process to completion.

180 gm. of crude calcium oxalate was thus obtained from about two hundredweights of each mineral. This oxalate was rigorously purified in accordance with the procedure of Hönigschmid and Kempter[1], to ensure the removal of all traces of barium and strontium, then converted to the nitrate and repeatedly recrystallised. Finally, the ratio $CaCl_2$: 2Ag was determined, using all the standard refinements of technique.

Six determinations with Rhiconich calcium gave an atomic weight of 40·092, with a probable error of 0·0006. Six determinations with Portsoy calcium gave an atomic weight of 40·089, with a probable error of 0·0004. Parallel experiments with calcium derived from recent marine sources—sea-shells and Bermuda limestone—gave values of 40·076 and 40·077 respectively.

From the above results, the radioactive half-period of the potassium isotope with mass 41 may be calculated on two limiting assumptions: (*a*) that all the calcium with mass 41 existent in the rock was extracted therefrom, and (*b*) that only one-third of this calcium was extracted. The resultant times are, on the former assumption, 2×10^{12} years (Rhiconich) and $1{\cdot}3 \times 10^{12}$ years (Portsoy); on the latter assumption, 7×10^{11} years (Rhiconich) and

$4{\cdot}3 \times 10^{11}$ years (Portsoy). The value indicated is thus of the order 1×10^{12} years, in definite agreement with the recent work of Mühlhoff[2].

Surface Tension of Colloidal Solutions, and the Action of Light on Soap Solutions

SOME time ago[1] a discussion arose between Prof. Mahajan and myself about the interpretation of a phenomenon which I described for the first time in 1922, namely, the slow decrease in the surface tension of colloid solutions in general, as a consequence of the adsorption in the surface layer. I showed that this decrease could be followed step by step by means of a proper instrument.

Prof. Mahajan questioned my interpretation of the mechanism of this phenomenon especially in the case of Boys's soap solutions, and suggested that it was due to the action of light, as he had noticed a difference whether the solutions were kept in the dark or not. I replied and, I believe, I succeeded in convincing him that the phenomenon in question was indeed due to adsorption in the surface layer, and of a much greater amplitude than that which might be attributed to the action of light alone.

Since then, I have had an opportunity of checking at the same time my statements and Prof. Mahajan's, and I found that, as I had suggested, the effect of light—which is real—was small in comparison with the main phenomenon, namely adsorption as a function of time. This being settled, credit must be given to Prof. Mahajan for his discovery of this effect. The figures given below will indicate the relative importance of the two factors.

Decrease of Surface Tension of Sodium Oleate solutions as a Function of Time
(Exp. Sept. 30, 1931)

	Solution kept in the dark and measurements made in the dark.	Solution exposed to daylight for 3 hours.
Decrease at concentration of 10^{-4}	3·3 dynes	6·2 dynes
Decrease at concentration of 10^{-5}	18·3 „	23·6 „

Here we observe a difference of 2·9 dynes and 5·3 dynes at two different concentrations, in favour of the solution exposed to light. The difference is not always so important: another experiment, at a concentration of 10^{-4}, gives a difference of 2·2, another one (Oct. 5, 1931) shows no difference at all (1·6 in both cases), and another still, shows a greater drop for the wrong solution. However, in general, there is a difference, and the difference increases when the dilution increases. At a concentration of 10^{-3} the difference may be of the order of 0·1 to 0·5 dyne, while it reached as much as 6·4 dynes, in one experiment, at 10^{-5}.

We must not forget, however, that when dealing with a soap solution at a concentration of 10^{-4}, the *measurable* dynamic surface tension of which is about 43 dynes, we are forced to neglect the first, and almost instantaneous drop from 73·7 dynes (pure water) to 43. When we deal with more dilute solutions (10^{-5}) the dynamic surface tension rises to 73 dynes—very close to that of pure water—and the observed drop amounts to as much as 26 dynes (in the dark).

To summarise, we can say that the drop in the surface tension of colloidal solutions in general, and in particular of soaps, is due as I have contended since 1922, to adsorption as a function of time, as predicted by elementary thermodynamic considerations, and as expressed by the Gibbs-Thomson equation.

To this general statement we can now add that Prof. Mahajan has shown that, in the case of soap solutions, light has an effect, and increases the amplitude of the decrease. The increase may reach the order of magnitude of 20–25 per cent of the total drop, when the solutions are highly diluted (10^{-5}). When the solutions are more concentrated, the phenomenon is less clear and sometimes even absent, and the percentage cannot well be expressed, as the measurement of the real dynamic surface tension is impossible.

Methionine in Wool

THE method of estimating methyl thiol groups devised by Kirpal and Bühn[1], and Pollak and Spitzer[2] (analogous to the Zeisel process for the estimation of methoxy groups) has recently been used by Baernstein[3] for methionine estimations in a study of the sulphur distribution in a number of proteins. In a subsequent paper, Baernstein[4] refers to the work of Rimington[5] and the writer on the cystine content of keratins, in which it was shown that these substances contain enough cystine to account for nearly all this sulphur, and presumably as a consequence, he did not carry out any determinations of methionine on keratin.

King[6], in discussing the sulphur economy of animal fibre production, has pointed out the possible significance of methionine as a thiol body concerned in the auto-oxidation of glutathione, and thus from these two points of view more definite information as to the amount of this acid in wool becomes of some interest.

Some determinations on wool have been carried out by the author as described by Baernstein, with minor modifications, and with the few wools so far examined, the methionine content is of the order of 0·5 per cent on the dry weight on the keratin. Mueller[7] has actually isolated methionine from wool to the extent of about 0·2 per cent.

In considering the effect on the relationship between total sulphur and cystine sulphur in keratin of this quantity (0·5 per cent) of methionine, which corresponds to approximately 3 per cent of the total sulphur[8], it may be regarded as doubtful if such a discrepancy would be revealed by the Folin-Marenzi technique for cystine determination.

Moreover, recent work of Butz and du Vigneaud[9] shows that methionine, though not reactive to the Folin-Marenzi reagent itself, gives on hydrolysis with acids (particularly with sulphuric and to a lesser degree with hydriodic) 'homo-cystine', the next higher homologue of cystine, which is reactive to the Folin-Marenzi reagent.

Thus although it appears that methionine may be present in wool keratin to the extent of 0·5 per cent (and the possibility of other sulphur acids occurring in small amount must not be overlooked) it does not influence unduly the previous conclusion of Rimington[4] and the writer, that substantially the whole of the sulphur in keratin may be accounted for as cystine, even though some methionine, because of its hydrolysis to 'homo-cystine', may have been previously recorded as cystine when using the Folin-Marenzi technique.

The complete distribution of sulphur in keratins will be more readily realised when more precise methods are available for the determination and isolation of cystine.

Priestley as a Practical Chemist

WITHOUT wishing to be captious, may I say that the statement by Prof. Meldrum at the Chemical Society on April 6 (NATURE, April 15, page 555) that Priestley had confessed himself "not a practical chemist", seems to me to convey rather a wrong impression, because I fancy that by the term *practical chemist*, Priestley meant something a little different from what we nowadays would mean by the expression.

In the passage in which the phrase occurs ("Experiments on Air", 2nd edition. 1776. Vol. II, page 1) Priestley says he "*had no access to any person of that profession*" and on page 51 speaks of having got Dr. Higgins to make him a quantity of red lead. From these, and other passages, I fancy he meant by the term *practical chemist*, a person who made his living by the preparation and selling of chemical compounds—a professional chemist.

Priestley was an amateur, and might very well have claimed to be—though I do not know if he did so—an *experimental chemist*, which is much the meaning of *practical chemist* at the present day, and, in this sense of the term, Priestley was perhaps the most practical chemist that ever lived.

Upper Limit in Explosive Chain Reactions

THE existence of an upper limiting pressure for explosion in thermal chain reactions has been explained in two ways. (1) The rate of branching of the chains, at the limit, is just sufficient to balance the rate of gas phase deactivation of the carriers; (2) a sudden change in the nature of the absorbed layer of gas on the walls of the reaction tube leads to the ejection of atoms or molecules into the gas capable of starting the chain. In two recent letters[1] to NATURE, the gas phase deactivation theory has been further extended to explain the occurrence of the upper limit. It may be of interest, therefore, to describe an experiment with phosphine-oxygen mixtures in which it can be shown that in the region above the upper limit there is a gradual decrease in the length of the reaction chains as the pressure is increased.

In order to initiate the chain, dissociation of the phosphine molecule was effected by collision with an optically excited ($2\,^3P_1$) mercury atom[2]. The pressure of the phosphine was maintained at a constant value (0·130 mm. mercury) and a series of experiments was made at different oxygen pressures with the mercury lamp burning at a constant intensity. As can be observed from Fig. 1, the rate of reaction increases at first, reaches a maximum and then decreases; and the pressure of oxygen at the maximum is of the same order as that where the curves representing the upper and the lower limit coincide[3]. The chain length consequently increases in the region below the lower limit, but above the upper limit it apparently decreases as the pressure of gas rises.

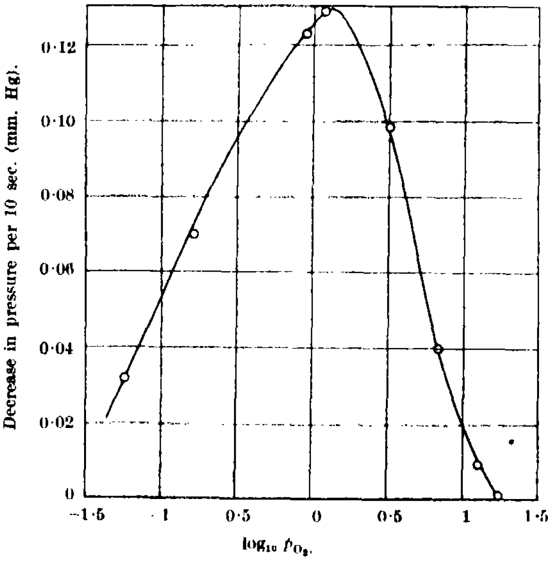

FIG. 1.

It might be argued that this decrease in chain length is due to deactivation of the mercury atoms by oxygen as the oxygen pressure is increased. Taking this factor into account, the rate of oxidation of phosphine is then given by

$$R = -\frac{d[\mathrm{PH}_3]}{dt} = \frac{K_1 k_1 [\mathrm{PH}_3]}{k_1[\mathrm{PH}_3] + k_2[\mathrm{O}_2] + 1/\tau} \cdot K_2[\mathrm{PH}_3] f([\mathrm{O}_2]),$$

the first term representing the rate of starting and the second the chain length; k_1 and k_2 are velocity coefficients and τ the mean life of the excited mercury atom. If $f([\mathrm{O}_2]) = [\mathrm{O}_2]$, as is probably the case below the lower limit, R would increase with $[\mathrm{O}_2]$ and tend to a maximum steady value when $[\mathrm{O}_2] >> [\mathrm{PH}_3]$. The fact that R decreases shows that $f([\mathrm{O}_2])$ is of the form $1/[\mathrm{O}_2]^n$ and hence the chain length must decrease as $[\mathrm{O}_2]$ increases. From the results, it may be readily shown by plotting $1/R$ against $[\mathrm{O}_2]^2$ that n approaches unity. The oxygen molecule is thus an inhibitor for the reaction in this region by virtue of its deactivating influence on the chain carriers in the gas phase. As the upper limit is approached, such deactivation diminishes until the rate of branching effects a balance between the two, and explosion occurs.

Interaction Between Soot Films and Oil

IF a piece of glass, say a 3 in. × 1 in. microscope slip, is thinly smoked in a luminous flame, allowed to cool and a drop of oil allowed to fall from a height of a few centimetres on to the film, a circular pattern is formed immediately, radiating from the centre of the drop. This figure usually has a central part of concentric striæ of soot, surrounded by a circle of clear dots formed by the withdrawal of soot and its concentration at their peripheries. These dots are surrounded by a further region of rather larger dots with an outer annulus of smaller ones, all formed by the concentration of soot into the surrounding areas. Breaks in the outlines in places show that the figure is strained. Outside the figure, annular regions of attenuation and concentration may be observed. The figure is usually about 0·5 cm. in diameter but varies with the size of the drop. The structure is strong enough for the oil to be washed off the glass with an appropriate solvent, when it may be preserved by mounting *in situ* with Canada balsam-xylene. It may also be formed by letting balsam, instead of oil, fall on the smoked slide.

The following liquids have been found to yield patterns: medicinal paraffin, which is very viscous, castor oil, cotton-seed oil, olive oil, and ordinary paraffin. Peripheral disruption was shown by bromoform, pentachloroethane, chloroform and nitrobenzene. Aniline yielded a pattern with central disruption and radiating effects. Cyclohexanol and cyclohexanone yielded patterns. With glycerol and with sulphuric acid, disruption of the film occurred.

Observation of the film as the drop falls shows that an evolution of gas occurs, the gas bubbles being responsible for surface stresses which drag the film away from the glass under them. Both new films and films formed overnight yield patterns. As oil which has been recently boiled forms patterns, it would appear that the gas is adsorbed by the soot as the film is formed and is not that dissolved in the oil.

I have not seen this effect described; if it had been, it would surely have been well known to microscopists, as the patterns form very beautiful objects under a magnification of from 20 to 50 diameters. They are easily visible to the naked eye and most of the structure can be seen under a hand lens. The general appearance is like a plant section or a coarse circular diatom.

Production of Electronic Oscillations with a Two-Electrode Valve

IN 1920, Barkhausen and Kurz discovered that an ordinary three-electrode valve could be made to give rise to oscillations of very high frequency (greater than 3×10^8 cycles per second) if the grid was maintained at a relatively high positive potential while the anode was made slightly negative with respect to the filament. The explanation for the occurrence of such oscillations appears to be that a condition of negative resistance is possible when the electrons are given a to and fro motion within the valve. It occurred to me some time ago that such a vibratory motion of electrons should be obtainable from a two-electrode valve of special design but circumstances prevented the construction of the valve until recently.

The valve, constructed by H.M. Signal School, Portsmouth, consists of a central metal rod anode of 1 mm. diameter around which are arranged four filaments in parallel spaced equally on a ring 12·5 mm. diameter. When the filaments are heated and the anode is maintained at a high positive potential, the electrons are attracted from the external cathode towards the anode. A certain number of electrons, however, escape capture by the anode and travel towards the filament diametrically opposite to that from which they were emitted. In this way the necessary to and fro motion of the electrons may be obtained in a diode without any external field being necessary as in the case of the magnetron. Preliminary experiments have shown that the valve behaves in exactly the way predicted and strong oscillations have been obtained. Another important feature is that by means of a tuned external circuit the frequency of the oscillations appears to be adjustable within fairly wide limits while all other operating conditions are kept constant.

A two-electrode valve of somewhat similar design has recently been described by J. Sahánek[1], but he gives a different explanation for the occurrence of oscillations.

Structure of the Lines of the Arc Spectrum of Silver

THE fine structure of the more important lines of the arc spectrum of silver was examined by means of a reflecting echelon grating of high resolving power. This instrument and its mounting have been previously described[1]. The light source was a tube of fused silica fitted with external electrodes similar to those used by me in the investigation of the structures of the arc lines of indium[1], thallium[2], and gallium[3], excited by means of a high frequency oscillator. The discharge tube was filled with neon at a pressure of about 0·5 mm. of mercury, and the capillary portion of the tube contained a small quantity of silver chloride. The capillary was heated to a temperature of about 600° C. All the lines examined were found to be simple. The half-value width of the lines was determined by obtaining two images of the line under investigation on the same plate, making two exposures at different pressures of the air surrounding the echelon grating; the separation of the images at the smallest pressure difference at which the two images could still be resolved was measured and taken to be the half-value width of the line.

Now the half-value width of a line with no fine structure (a simple line) due to the Doppler effect arising from the movement of the atoms is equal to $\nu \times \sqrt{\theta/M}/1{\cdot}2 \times 10^6$, where ν is the frequency of the line, M is the atomic weight and θ the absolute temperature of the radiating atoms. In the following table the observed half-value width of the lines examined is compared with the calculated width for a simple line.

Line	3280 $1S_{1/2}$-$2^2P_{3/2}$	3380 $1S_{1/2}$-$2^2P_{1/2}$	5209 $2^2P_{1/2}$-$3^2D_{3/2}$	5465 $2^2P_{3/2}$-$3^2D_{5/2}$	5471 $2^2P_{3/2}$-$3^2D_{3/2}$	4055 $2^2P_{1/2}$-$4^2D_{3/2}$	421 $2^2P_{3/2}$-$4^2D_{5/2}$
Observed half-value width of line	0·07 cm.$^{-1}$	0·07 cm.$^{-1}$	0·04 cm.$^{-1}$	0·04 cm.$^{-1}$	0·04 cm.$^{-1}$	0·05 cm.$^{-1}$	0·05 cm.$^{-1}$
Calculated width of simple line	0·07 cm.$^{-1}$	0·07 cm.$^{-1}$	0·04 cm.$^{-1}$	0·04 cm.$^{-1}$	0·04 cm.$^{-1}$	0·05 cm.$^{-1}$	0·05 cm.$^{-1}$

None of the observed lines has a greater width than that calculated for a simple line. It can therefore be concluded from the observed width of the lines of the diffuse series that any structure in the terms $2^2P_{1/2}$, $2^2P_{3/2}$, $3^2D_{3/2}$ and $3^2D_{5/2}$ must be less than 0·04 cm.$^{-1}$; and from the width of the resonance lines, any structure in the $1S_{1/2}$ term must be less than 0·07 cm.$^{-1}$ (The triplet structure observed by Mohammad and Sharma[4] in the resonance lines is due to self-reversal of the lines given by the vacuum arc lamp they used and also a ghost in the Lummer plate fringes in the ultra-violet.) This simplicity of the $1S_{1/2}$ term is of the greatest interest for it signifies that any doubling of this level arising from magnetic moments of the nuclei of the silver isotopes must be smaller than 0·07 cm.$^{-1}$ This seems to indicate an abnormally low magnetic moment of the silver nuclei; for the $1S_{1/2}$ term of copper has a doublet structure with a separation of about 0·3 cm.$^{-1}$, and since the $1S_{1/2}$ term of silver corresponds to a more penetrating orbit, it would be expected that, if the silver nuclei possessed magnetic moments comparable with those of the copper nuclei, the $1S_{1/2}$ term of silver would possess a doublet separation of the order of 0·5 cm.$^{-1}$

It has been suggested to me by Dr. S. Tolansky that the absence of structure in the deeply penetrating $1S_{1/2}$ level does not prove that the magnetic moments of the silver nuclei are abnormally small. In the spectrum of thallium, the $2S_{1/2}$ and $2^2P_{1/2}$ terms possess large hyperfine structures, while the $2^2P_{3/2}$ term, which corresponds to an almost equally deeply penetrating orbit, possesses no observable structure. No explanation of this anomaly has been found, and it must therefore be considered possible that, owing to a similar cause, a normal magnetic moment of the nuclei gives rise to no observable structure in the $1S_{1/2}$ term of silver. The absence of fine structure could also be explained by ascribing a mechanical moment of 0 to the nuclei of silver; but this seems to be improbable as silver possesses two isotopes of odd atomic weight (107 and 109) and all atoms of odd atomic weight hitherto investigated have been found to possess mechanical moments.

Fine Structure of the Resonance Ag I Lines

THE structure of the silver lines 3280 A. and 3383 A. have been examined with Lummer plates by W. Mohammad and P. N. Sharma[1] using a specially constructed vacuum arc. They report identical triplet structures of intensity ratio 5 : 5 : 1 and separations of 0·218 and 0·116 cm.$^{-1}$ respectively, the weaker component being on the violet side. They therefore attribute this structure to the common $5s^2S_{\frac{1}{2}}$ term, which, with a J value of $\frac{1}{2}$ should only give a fine structure multiplicity $2J + 1$ when $J \ll I$. A triplet could only arise if there were an isotopic displacement effect and provided the g (I) factors of the nucleii differed so that two of the four components superposed. In this somewhat unlikely event the intensity ratios should be very different from the values quoted above since the abundance ratio is unity. This, however, would not be a serious contradiction since it is well known that intensity measurements with resonance lines are necessarily unreliable owing to self-absorption.

We have examined these lines with 25 and 35 plate reflection echelons, employing water and liquid air cooled hollow cathode discharges. Two hollow cathodes of 8 mm. internal diameter and 15 cm. length were used, the one consisting of 5 per cent silver and 95 per cent cadmium, the other with the proportions reversed.

With both cathodes, the two lines appeared single, of a total width not exceeding 0·050 cm.$^{-1}$, when the discharge current was low (0·1 amp.). As the current was increased these particular lines broadened while the other lines remained equally sharp. With the silver cathode a sharp reversal occurs at about 0·2 amp., the width of the clear centre band steadily increasing with heavier currents until, with a current of 0·8 amp., the separation between the wings of the reversed line amounts to 0·13 cm.$^{-1}$. With the cadmium cathode the current could be increased to 0·4 amp. without reversal.

It may be concluded, therefore, that the structure observed by Mohammad and Sharma is a case of self-reversal due to the unsuitability of the vacuum arc source. The total structure width of the lines must be appreciably less than 0·050 cm.$^{-1}$

The peculiar absence of structure in these and other Ag I lines is explained in a forthcoming paper (*Proc. Phys. Soc.*) by Dr. Tolansky, who infers that it is due to anomalous external electron coupling, and not necessarily to zero spin or small magnetic moment.

The 'Tail' of the Male American Toad, *Ascaphus*

Ascaphus (North America) and *Liopelma* (New Zealand) constitute, according to Dr. G. K. Noble, the Liopelmidæ, the most primitive anuran family in existence. Apart from the importance of *Ascaphus* from the general phylogenetic aspect, it has often been credited with possessing a tail. Noble has described a pair of tail-wagging muscles for the genus. Moreover, *Ascaphus* possesses a prepelvic skeletal structure of the nature of a prepubis (or epipubis) and is further notorious in possessing post-pelvic 'Nobelian cartilages' (Mehelij). Presumably the epipubis and the Nobelian cartilages represent chondrifications of the pre- and post-pelvic portions of the linea alba respectively. The latter are known in *Ascaphus* only.

The microtomised pelvic region of *Ascaphus* reveals the following features: (1) the frog has the epipubis in the form of an inverted Y, the arms of which are synchrondrotically fused with the pelvic girdle, whereas in *Xenopus* the epipubis is merely articulated with the girdle. Presumably the structure is a derivative of the linea alba as in *Xenopus*, whereas some Urodeles have a prepelvic element developing as a zonal derivative, and therefore not homologous with an epipubis. The Nobelian 'cartilages' *prove to be true bones* with enormous marrow cavities. Their ontogeny is unknown, but they look suspiciously like sesamoid bones (tendon bones). The cloaca is continued into the tail, at the end of which it has a groove-like opening. The cloacal opening has large dermal proctodeal glands. The 'tail' is a mass of spongiose fibres, the interstices of the network filled with blood. This erectile tissue is distributed into a pair of strands ventral to the cloaca and lateral to the Nobelian *bones*, and a strand is pierced by the cloaca. The skin is separated from the erectile tissue by large subdermal lymph spaces, but is adherent ventrally and mid-dorsally.

There is no doubt that the 'tail' of the male *Ascaphus* is an intromittent organ with highly developed erectile tissue comparable with that of the penis. If the genus is really very primitive, the cloacal region in the male may be of very great importance for the evolution of the omniote reproductive system.

The Neuro-Muscular Junction and Curare

WHEN, some years ago, I suggested[1] that the phenomena associated with the action of drugs on muscle might more appropriately be explained by reference to the actual facts of minute anatomy than to a hypothetical 'neuro-muscular junction', what I had in mind was the histological conditions present at the eminences of Doyère and not the "part of the nerve which is exposed to the action of the drug, namely, its ending where the medullary sheath is absent". The situation, to which Prof. A. V. Hill refers in his article on "The Physical Nature of the Nerve Impulse",[2] is not materially different from any other node of Ranvier (it is only a node of Ranvier), and the axis core is here consolidated and compact. At the eminences of Doyère it is, on the contrary, considerably subdivided beneath the expansive surface of the sarcolemma, and is accessible to the action of drugs.

The result of Fromherz's experiment is consistent with this view, but scarcely with the view that curare acts on the part of the nerve mentioned by Prof. Hill, since numbers of precisely similar parts are contained within the length of nerve subjected to experiment after removal.

I make this comment on a detail of Prof. Hill's interesting paper because the point is capable of further development. The transformation of the nervous material from a dense to an attenuated state is carried a stage further within the muscle fibre proper, a fact which should receive more attention than has yet been accorded to it if the physical nature of the muscular contraction is to be understood in correlation with the actual mechanisms which subserve it and not merely in correlation with associated phenomena.

While it is desirable that the histological accounts of muscle and nerve should be pruned of their many inaccuracies and irrelevancies, may I suggest to Prof. Hill that the existence of what are called 'end-plates' is not dubitable by those familiar with muscle histology?

Some Limiting Factors in the Environment of the Common Limpet, *P. vulgata*

THE relation of the organism to the environment, especially to limiting factors in the environment, is a subject of much importance to the student of bionomics, hence the following observations made in 1932 are considered worthy of record.

On the morning of August 28, 1932, at about the end of the period of hot dry sunny weather, dead, dying and weak limpets, *Patella vulgata*, were found at about high-water neap-tide level on a platform of cliff at Stepper Point, near Padstow. The dead and dying limpets (about 3 cm. long) were found both in and at the edge of healthy-looking pools which were lined by a pink encrusting calcareous alga (*Lithothamnion* or an ally). Around these pools and exposed to the air was a rim of white dead alga on which were numerous dead *Patella*, some having *dried-up* bodies. Suspicion that the pools may have been polluted—although pollution alone would scarcely suffice to explain the dead limpets on the rims—led to an examination of limpets at higher levels. It was then found that much larger limpets whose 'homes' were out of water were so weak that one could easily lift them off the rock slowly with a silver fruit-knife, whereas ordinarily a stout potato knife is barely strong enough to remove them even when plunged suddenly under the edge of the shell. The occurrence of these weak limpets enhanced the probability that the reduction in the level of the pools was natural, and led to the examination of more alga-encrusted pools in the locality, where more dead limpets were found, especially in the dried-up rims. There seems little doubt therefore that evaporation had exposed the rims of pools and the pool-limpets to the air. A few days later limpets in this locality—after immersion in sea-water during the increasing tides—were firmly seated on the rock.

The pools were situated at about the level of high-water neaps where usually the splash of the waves would renew the water even at neap tides, but on August 28 it is clear that the pools had remained stranded from some unusual cause, since many of the limpets had dried-up bodies. An explanation is suggested by an examination of the Admiralty Tide Tables and a consideration of local conditions.

The sea had maintained in the locality a continuous and arrestingly noticeable flat calm for some days previously; such light winds as occurred being offshore. It also happened that the period coincided (*a*) with low (summer) H.W. neap tides, August 25-28[1], and (*b*) with rather warm weather[2]. Thus the absence of renewal of the water extended over an unusually long and warm period and caused the limpets to be exposed to hot weather conditions at midday. It is known that limpets may not be wetted during a few successive neap tides in calm weather[3], but the exposure during a set of neap tides following the normal midday exposure at low water of spring tides would impose a severe strain upon the animals.

The death of the limpets on the rim of the pools therefore followed an unusual exposure to sun and air, while those succumbing in the pools had doubtless been subject to large and complicated variations in the little-known co-existing physical and chemical conditions[4]. At the same time limpets accustomed to exposure higher in the foreshore survived, though in a weak condition. These facts confirm the critical nature of the environment round about the level of H.W. neaps[5]. Limiting natural environmental conditions—unfortunately not closely definable—in temperature, humidity, certain chemical and other physical factors were therefore either approached or surpassed in this locality for *P. vulgata* in August 1932.

Measurement of Light for Biological Purposes

THE measurement of light intensity has always presented certain difficulties to biologists, especially when it was necessary for the measurements to be made under field conditions. The available methods were either slow, or measured only limited spectral ranges, or else involved the use of cumbrous apparatus of limited portability. We have lately used, however, a form of apparatus which seems to be free from these disadvantages. We are so impressed with the usefulness and simplicity of this apparatus that we wish to bring it to the notice of readers of NATURE and particularly to that of biologists.

The essential part of the apparatus is a Bernheim photo-voltaic cell. The current produced by exposing this cell to light is measured by the deflection of a Unipivot galvanometer, which is sufficiently robust to be read easily in a small boat and has already travelled many hundreds of miles in a motor-car over bad roads. A manganin resistance of 1,000 ohms is put into the circuit for readings in full daylight. There is no lag in the readings and there is no dark current. Moreover, there is no reversal of the current at certain spectral ranges, as may be the case in some rectifier photo-cells.

Using this cell enclosed in a watertight container we obtained the following measurements of light penetration in Windermere. For comparison with the figures so obtained are given those measured with a recent form of potassium-on-copper vacuum cell. In using the latter, it is necessary to amplify the primary photoelectric current about two hundred times in order to obtain readings comparable with those of the Bernheim cell. The thermionic potentiometer devised to accomplish the amplification and measurement is naturally somewhat bulky and less readily portable.

Light intensity at different depths in Windermere.
February 8, 1933.

Depth in m.	1	2	3	5	7	9	11	13
Bernheim cell	38·0	19·9	11·1	3·84	1·33	0·45	0·15	0·052
Vacuum cell amplified	36·3	15·9	7·41	1·82	0·43	0·11		

Values as percentages of full daylight.

The greater utility of the Bernheim cell for this type of work is due not only to its greater sensitivity but also to the fact that it is sensitive over the whole range of the visible spectrum. The cell we have employed for outdoor work has the following spectral sensitivity, given as galvanometer deflection per 1,000 ergs per cm.^{2} per sec. (for the facilities necessary to make these determinations we are indebted to Prof. R. Whiddington):

Wave-length in A.	3500	4200	5000	5700	6200	7000
Sensitivity	1·4	3·0	5·6	6·7	4·8	1·1

The vacuum cell used in the above mentioned measurements has a maximum sensitivity in the region 4000–4900 A. and only slight sensitivity in the red.

Preservation of Fossil Bones

UNDER the above heading in NATURE of March 11, p. 366, Mr. Ludovic McL. Mann states that the mammalian bones in the Kelvingrove Museum, Glasgow, "were all found . . . in the laminated gravels of the old raised terrace of the Kelvin river, some eight miles east of Glasgow, at about 170 ft. O.D."

Readers will probably interpret "raised terrace" as they are accustomed to interpret raised beach, that is, as a terrace originally formed at a lower level and owing its present position to relative elevation of the land. Certainly they will think that the gravel deposit in which the bones were found is a *higher* terrace of the River Kelvin, in the same way as the implementiferous terraces of southern England are higher terraces of the rivers occupying the valleys.

Recently, I have been studying the Kelvin valley terraces in an attempt to understand the glacial history of the Glasgow district. I think, with other geologists, that there is no connexion between the 170-ft. terrace of current-bedded sands and gravels and the present River Kelvin, other than that they occur in the same valley, referred to above as the Kelvin valley.

The late Prof. Gregory[1], on more than one occasion, gave a Mousterian age to the gravels of these terraces, but it is now clear that they must be very much more recent than the Early Magdalenian.

W. J. MCCALLIEN.

University of Glasgow.

Research Items

Woolly Hair in a Nordic Pedigree. An interesting case of an apparent mutation in hair character inherited as a simple Mendelian dominant through five generations in a Norwegian family has been described by Dr. O. L. Mohr (*J. Hered.*, vol. 23, No. 9). The hair is woolly or ulotrichous and short, closely resembling that of a negro but densely set. The individuals are otherwise of Nordic type and colouring, and all the circumstances render any crossing in the ancestry highly improbable. The descent is from a woman who married twice and left woolly-haired individuals in both lines of descent, the sibships numbering 38 woolly, 42 non-woolly and 3 unknown. The parents and grandparents of this woman are known, but not their hair characters. The woolly hair is flattened or kidney-shaped in cross-section and shows only traces of a medulla. It only reaches the length of negroid hair but is light in colour. This appears illuminating in regard to the origin of the ulotrichous races of mankind, as such hair is also dominant in racial crosses. The similarity cannot, however, be pressed too far, since in negro crosses the later generations show various degrees of the woolly condition. Nevertheless it helps to indicate how the ulotrichous character may have arisen, possibly independently, in Negro and Melanesian.

Destruction of Predatory Animals in Alaska. The past five years have shown in Alaska an increased destruction of predatory animals owing to the assistance and advice given to trappers by the local control leader of the Bureau of Biological Survey (Report for year ended June 30, 1932). In the year before control work was undertaken, 1925–26, 1,111 wolves and coyotes were presented for the 15 dollar bounty, and in 1927–28 the number was 2,161. In 1929–30, notwithstanding that the legislature reduced the bounty to 7.50 dollars on wolf and 5 dollars on coyote, there were 2,304 individuals presented. In 1931, with the bounty re-established at 15 dollars, though fewer private trappers worked in the Territory, reports to the Bureau show an increase in the catch over the preceding year of nearly 70 per cent.

Penguin Embryos. C. W. Parsons has described the series of penguin embryos, 64 of the gentoo and 14 of the ring penguin, collected by the "Discovery" Expedition (Reports, vol. 6, 139–164; 1932). The earliest embryo corresponds with an embryo of the fowl of 24 hours incubation; the latest is a ring penguin about six inches long, fledged in the coat of silky down with which it hatches. The intervening embryos are arranged in six stages. A description of the more outstanding features of each of the eight stages is given and is followed by comparative studies on the brain, feathers, and cartilaginous skeleton. In the brain, one of the notable features is the precocious development of the pineal body and for a time its disproportionate size. The last feather rudiments to appear are those on the wings. The author comments on the controversy as to whether feathers can be derived, like scales, from conical skin papillæ and refers to the granular type of skin reproduced in the earliest feather papillæ "as being a likely characteristic both of the ancestors of birds and of the scaly reptiles". In the skeleton the cartilages of the fore-limb grow at a prodigious pace. The author remarks that the body of the penguin, with its back arched and its limbs hanging vertically, is extraordinarily reminiscent of the aquatic reptiles of Mesozoic age. Small transitory papillæ which appear on the dorsal side of the lung are interpreted as incipient air-sacs which do not proceed with their development; air-sacs in that position would be hemmed in between the distended lung and the unyielding dorsal wall of the cœlomic cavity and in time would be eliminated. The development of the heart is traced in some detail. The paper is illustrated by text figures and by six admirable plates.

Tintinnids of Mutsu Bay. Much of the fauna and flora of Mutsu Bay has been described already systematically in the Science Reports of the Tôhoku Imperial University (Reports of the Biological Survey of Mutsu Bay). Vol. 8, No. 4, November 1932, contains the Stomatopoda, Cirripedia and the pelagic Ciliata, suborder Tintinnoinea. The last, by Yoshine Hada, includes a large number of species obtained by the author himself in surface collections and vertical hauls at numerous stations, August 1929–September 1930, and plankton collected with a surface tow-net twice a month in 1927–31 and preserved in the Asamushi Marine Biological Station of the Tôhoku Imperial University. Tintinnids form a very important part of the unicellular plankton and their importance is being recognised more and more, for they are the food of innumerable small marine animals swimming in the surface layers, from Protozoa to young fishes. From this region, thirty-four species belonging to twelve genera and eight families are recorded, seven species being new to science. The most predominant genus is *Tintinnopsis*. Some of the genera *Tintinnopsis* have a wide distribution and such a well-known species as *Tintinnopsis beroidea*, common in British waters, abounds in Japanese seas in February–April and September. The family *Tintinnidæ*, the members of which assume comparatively large dimensions in warm waters, is represented by only four species, but three of those recorded are common, including a new *Tintinnus* closely related to *Tintinnus tenuis* Kofoid and Campbell, and both of these occur abundantly. The paper is illustrated by clearly drawn text figures of the lorica of most of the forms.

Root Systems of Fruit Trees. The results of modern research are revealing many striking facts about the extent of the root systems of various plants. Older ideas about shallow-rooted and deep-rooted plants do not seem to hold. A recent paper by Mr. W. S. Rogers ("Root Studies III", *J. Pomol. and Hort. Sci.*, 11, No. 1, 1–18, March, 1933) shows not only that the roots of gooseberries penetrate the soil to a depth of 8 ft. but also correlates root development with manurial treatment. Pears and black currants were also studied. Roots of the former reach a depth of 11 ft. and of the latter 7 ft. Pears grafted on seedlings were compared with those grafted on Angers quince. The seedling roots consisted of a large number of main roots going almost vertically downwards, whilst quince roots form a horizontal 'scaffolding' from which fine roots descend. Heavy manuring with farmyard manure increased the total amount of root produced, but tended to make the system more compact.

Plant Geography of Ulijanowsk. This part of Russia in Europe lies south of the middle reaches of the Volga. The variation in natural conditions within this area causes great diversity in the vegetative covering. Most of the forests are pine, or subsidiaries resulting from felling, and are classified into the *Pinetum querceto-tiliosum* type growing on the higher and wetter places, and the *Pinetum querceto-sub-stepposum siccum* type. The composition of these forests and the undergrowth, including the grassy soil covering, has been examined by H. Grosset (*Bull. Soc. Nat. Moscou*, 41, Nos. 1–2). The study terminates with a short discussion on the steppe vegetation. The author emphasises the value of a consideration of the vegetation of areas in schemes of agricultural development. Water is the limiting factor in crop production, and, as the same amount of rainfall may give different effects according to the nature of the soil, the vegetation is suggested as a means of detecting biologically equivalent areas.

Land Bridges of Gondwanaland. In the *Bulletin of the Geological Society of America*, 1932, Prof. C. Schuchert deals with Gondwana land bridges (pp. 875–915), and his discussion is followed by a paper on isthmian links by Prof. Bailey Willis (pp. 917–952). Both papers are admirably illustrated by coloured maps. As the result of some thirty years' study of the palæontological evidence, Schuchert concludes that (*a*) the marine life of southern North America and southern Europe, and of South America and Africa, from the Silurian to the end of the Miocene; (*b*) the distribution of the land plants and animals from the Permian to the Cretaceous; and (*c*) the discontinuous localisation of recent life in Africa and South America, are overwhelmingly in favour of the existence of the Gondwana land bridge up to the end of Cretaceous time. The submergence of the bridge is thought to have taken place from the Eocene to the close of the Miocene, and it is considered likely that during this time there may have been a South Atlantic archipelago. Willis discusses the orogenic processes that may have been responsible for the formation of bridges such as the Isthmus of Panama, arguing from this particular case that marginal upthrusting has been due to expansive forces originating in adjoining basins and deeps. Similar "isthmian links" of the past are traced between Africa and India; Asia and Australia; and Africa and Brazil, along the lines of present-day submerged ridges and island chains. Assuming some general cause of moderate refrigeration, an attempt is made to show that the diversity of Permian climates in the northern and southern hemispheres is not inconsistent with the atmospheric and oceanic circulations controlled by the postulated "isthmian links" of that period.

Katabatic Winds. In spite of all that has appeared during the past few years dealing with katabatic winds, there is evidently still a large field of research into these and other winds that arise during the night when cooling of the lower layers of the atmosphere tends to isolate them from the upper 'free' atmosphere. S. Atmanathan (India: Meteorological Department. *Scientific Notes*, vol. 5, No. 46: Calcutta: Government of India Central Publication Branch, 1932; 10 annas; 1*s*.) describes the occurrence at Poona of a curious type of squall which he calls a solitary gust. These are sudden onsets of wind from the direction of the gradient wind that interrupt intervals of calm separating periods during which katabatic winds are blowing, and last from three to fifteen minutes. In most cases the squall is accompanied by a slight rise of pressure, and no subsequent fall; temperature generally falls temporarily during the squall, sometimes by so much as 4° F. This is a very unusual accompaniment of a sudden increase of wind on a clear night, and seems to rule out the possibility that the effect may be due to the gradient wind suddenly undercutting the cold surface layers. The author makes a tentative attempt to explain matters with the aid of mathematical dynamics, following Margules, but it is doubtful whether the observational material is complete enough for this, to mention only one obstacle to such an undertaking. Another difficulty of explanation arises from the fact that the usual direction of the gradient wind agrees roughly with the trend of the valley. He seems justified, however, in concluding that the phenomenon is in some respects analogous to a tidal bore—a surge of colder air of slightly higher pressure up the valley from the regions fed by the normal katabatic wind.

Anomalous Absorption of γ-Rays. B. Arakatsu has made (*Mem. Sci., Taihoku Imperial University*, Dec. 1932) an interesting suggestion to account for the anomalous absorption of γ-rays, observed by Tarrant, Chao, and others as an excess absorption for the heavier elements over that predicted by the Klein-Nishina formula for electronic absorption. This excess has usually been regarded as nuclear in origin. Arakatsu ascribes the effect to the extranuclear electrons, and he suggests that the rest-energy of these electrons may be capable of quantum jumps. He regards the electrons as wave-mechanical systems the energies of which may be calculated like those of a two-dimensional oscillator. The electrons taking part in the process are supposed to be those lying within a radial distance of the nucleus which is less than a half wave-length of the quantum radiation from a 'jumping electron'. The density of these electrons is obtained by the method of Thomas and Fermi, and the additional absorption is found to vary with the atomic number in fair accord with experiment.

Effects of the Addition of Tellurium to Lead. A paper read by Messrs. W. Singleton and Brindley Jones before the Institute of Metals on March 8 dealt with the chemical and mechanical effects of the addition of tellurium to lead to the extent of say 0·07–0·10 per cent. It is shown that such alloyed lead has a greatly increased resistance to attack by sulphuric acid, actual plant tests indicating that the loss of weight is only one-seventh of that of the most resistant chemical lead hitherto produced. Chemical lead is known to recrystallise spontaneously after strain at room temperature, and cannot, therefore, be hardened in that manner. With more than about 0·1 per cent. of tellurium, the product shows no softening through cold rolling after 140 days, with the result that tensile strengths up to about 4,000 lb. per sq. in. can be obtained in cold-rolled sheets. The degree of ductility associated with this tensile strength is good. On annealing after cold work the alloyed lead shows a relatively very fine crystal size as compared with that for the lead itself. The alloy can be extruded normally when both the strength and elongation are distinctly greater than those of the pure metal, and with slow rates of straining the elongation may approximate to 100 per cent. The fatigue limit of the tellurium-lead is of the order of ± 0·5 tons per sq. in., nearly three times that of ordinary lead. Tests made on the resistance of pipes to bursting by frost, showed that the addition of tellurium greatly improves the material. It is stated, though no actual results are given, that the addition of tellurium to lead alloys exerts similarly beneficial effects.

Sewage Purification by a New Process. The problems of sludge disposal and effluent purification are still troubling inland municipalities in most civilised countries, and though this century has seen many improvements in detail, the broad problems remain unsolved. A novel process has recently been developed in New York, which originated in the desire of Messrs. Guggenheim Brothers to find a new outlet for sodium nitrate. The desire has not been fulfilled, but G. H. Gleason and A. C. Loonam, on behalf of the firm, have succeeded in devising a system of purification and disposal that demands the attention of all concerned. The principles of their system consist in clarifying the sewage by precipitation with ferric sulphate and lime, filtering and burning the sludge, recovering the ferric sulphate by treating the ash with sulphuric acid, and purifying the effluent by means of the base-exchange material, zeolite. During the precipitation process, air is passed continually through the liquid to keep the iron in the ferric state, and careful control of the hydrogen ion concentration, at pH 6–8, is essential for success. Ferric iron, followed by lime, was found to be the best precipitant. In the base-exchange process, the basic nitrogen in the organic compounds present in the effluent is exchanged for the sodium in the zeolite, and when the latter is spent, it is regenerated by washing with a 20 per cent solution of sodium chloride. The nitrogen compounds in the brine are decomposed by distillation with lime and the ammonia is recovered, whilst the purified brine becomes available for further use. Tests on a plant treating 2,500 gall. of crude sewage a day have given excellent results, and a plant of ten times this capacity is now being installed at Chicago. The proprietors of the process are sanguine that capital and operating costs will compare very favourably with those of existing processes.

Astronomical Topics

Periodic Comet Pons-Winnecke. This comet attracted much attention in 1921 and 1927 from its near approaches to the earth, the least distances being 12 and 3½ million miles. Since 1927, it has made a close approach to Jupiter, which has increased the perihelion distance by six million miles, so that there will be no more approaches to the earth so close as that of 1927, which was the second closest approach on record; the closest was Lexell's comet in 1770, the distance being 1½ million miles; but this proximity was not known until later.

The first to observe comet Pons-Winnecke at this return was Dr. A. Wachmann at Bergedorf; the following two positions were obtained there from photographs taken with the Lippert astrograph (*Beob. Zirk.* No. 12):

U.T.	R.A. (1933.0)	N. Decl.	Mag.
March $24^{d}2^{h}55{\cdot}0^{m}$	$17^{h}44{\cdot}0^{m}$	9°27′	14
25 2 2·6	17 47·3	9 22	14½

The indicated date of perihelion passage is about May 18·7; the comet will be nearest to the earth about the same time, its least distance being about fifty million miles; it should be within reach of moderate instruments this month. As the period is now 6 yr. 1 mon., there is likely to be a closer approach in 1939 than this year.

Photographing the Moon's Shadow on the Earth during the Eclipse of August 31, 1932. *Popular Astronomy* for April contains an article by W. M. Browne, of the U.S. Naval Observatory, Washington, in which he describes a successful attempt to photograph this shadow from an aeroplane, which was just outside the southern limit of totality. A cinematograph was used; at the beginning and end of the exposure, the camera was directed to a chronometer, so that the accurate time can be deduced for each part of the picture; the focus was altered before directing it to the ground. It was noted that one of Baily's Beads remained visible throughout, showing that the aeroplane was almost on the limit, but just outside it. To the eye, no definite edge of the shadow could be seen on the ground, but on developing the film it was found that some details on the landscape could be seen before and after totality, becoming invisible during totality, which lasted 9·4 sec. at the region photographed. As the predicted time was 14 sec., it is concluded that the predicted southern limit was 0·4 mile too far south; also mid-totality was later than the predicted time by 3·8 sec. The region was the town of Suncook, New Hampshire, six miles south-east of Concord.

Motion of the Spiral Nebulæ. The presidential address to the Royal Astronomical Society on this subject by Dr. Knox Shaw has now been published (*Mon. Not. Roy. Ast. Soc.*, Feb. 1933). When the first determinations of radial velocity were made, the high speed of the sun due to galactic rotation was not applied; this accounts for most of the approaching velocity found in the case of the Andromeda nebula. Early discussions seemed to indicate that the galactic system had a velocity relatively to the mean of the spirals of some 200 km./sec. towards the direction of Capricornus, as seen from the sun. However, when the correction for galactic rotation is applied, our own galaxy seems to have a small velocity referred to the mean of the others. This is not unexpected, since our galaxy seems to be unusually large and massive. The value actually adopted for the solar motion (due to de Sitter) was 286 km./sec. towards R.A. 314°, N. Decl. 66°. One rather surprising point is that the red spectral shift has an appreciable effect on the photographic magnitudes of the nebulæ, amounting to a quarter of a magnitude for the distant ones. It might have been expected that the shift would bring some ultra-violet spectrum into the visible region; but these nebulæ do not appear to have an ultra-violet spectrum strong enough to register on the plates.

Dr. Knox Shaw estimated the average peculiar motion of the nebulæ as about 140 km./sec. He also suggested that the individual members of the clusters of spirals are considerably fainter (some 0·9 magnitude) than isolated spirals. But more evidence is needed before this can be received with confidence.

Copepods of Woods Hole*

DR. CHARLES BRANCH WILSON has recently published a beautiful and important monograph which he dedicates to the late Richard Rathbun, assistant secretary of the Smithsonian Institution from 1897 until 1918*. This is a study of marine, brackish-water and fresh-water species of copepods, including those that are free-swimming, commensal, semi-parasitic and parasitic. The area studied is large, including the whole of Cape Cod, Mass., and all the islands south of it and those portions of the surrounding ocean between latitude 40° and 42° N. and between longitude 69° and 72° W. It lies at the latitude where the northern and southern faunas meet and overlap, and therefore contains representatives of three distinct plankton faunas, those of the area itself, especially of the ponds and beach sands which make up the bulk of the species, the northern species brought by currents from the Bay of Fundy, the Gulf of the St. Lawrence or even farther north, and the southern species brought from the tropical Atlantic and the Gulf Stream.

The number of species previously reported from the area is 148. The present work increases this to 373 including 178 genera, several of which are new, and there are many new species. It is based mainly on a collection made in this area by the late Dr. Rathbun during the summers and early autumns of the years 1881–85 inclusive. Some of the specimens were obtained by surface towing and the rest were taken during the trawling and dredging operations carried on by the steamers of the Bureau of Fisheries, the *Fish Hawk* and *Albatross*. In addition there is the entire collection of local copepods made by the Bureau of Fisheries, collections from fresh-water, brackish-water and salt-water ponds made by Dr. Rathbun and continued by Dr. Wilson and many specimens from the beach sands. The whole forms a unique collection which is specially valuable on account of the notes, particularly colour notes, made by Dr. Rathbun when the animals were still alive, many of the copepods having only been described previously from preserved specimens.

There are new records of numerous species which are only taken very early in the morning or late at night and an important addition to the 'gear' was a device known as the 'trawl wings' attached to the bean trawl which captures the small free-swimming animals often living in extreme abundance just above the bottom. Dr. Rathbun's dissections, microscopic preparations and drawings were also of much use, but this monograph could not have been written unless the author himself were an expert on the subject. Dr. Wilson is well known as such an expert and there is a large amount of his own work here and much that is original. A clear account is given of so many groups illustrated with neat text figures and plates that the volume may well serve as a textbook to workers in all lands, including as it does representatives from almost every copepod family with a large number of species figured and described and useful keys to the sub-orders, genera and species.

Amino-Acids, Proteins and Proteolytic Enzymes

By PROF. MAX BERGMANN, University of Dresden

II

THIS is perhaps a suitable moment at which to assess our knowledge of the proteolytic enzymes. It remains a fact that dipeptidase, aminopolypeptidase and carboxypolypeptidase are three distinct enzymes; for the present, we may retain these names, but only so long as we bear in mind that they do not truly express the characteristic properties of the enzymes. We have seen that there is a dipeptide of naturally occurring amino-acids (asparagyltyrosine) which is not attacked by any intestinal proteolytic enzyme; there is a dipeptide (tyrosyltyrosine) which is hydrolysed not only by dipeptidase but also by carboxypolypeptidase; finally there are dipeptides (glycyl- and alanyl-proline) which are resistant to dipeptidases but are attacked by polypeptidase. It is therefore clearly not the number of amino-acids in the molecule of a peptide which determines its susceptibility to a particular peptidase. The presence of free amino and carboxyl groups adjacent to the peptide linkage does not necessarily render the compound open to attack by dipeptidase, nor will aminopolypeptidase hydrolyse all peptides in which the peptide linkage adjoins a free amino but no free carboxyl group. On the other hand, the action of the latter enzyme is not always inhibited by the proximity of a free carboxyl group to the peptide linkage.

It is evident that we must take further circumstances into consideration before we can hope to define rigidly the conditions of action of the various peptidases; in particular, careful attention must be given to electro-chemical effects and to such structural features as the secondary or tertiary nature of the nitrogen participating in the peptide bond. The accumulation of facts bearing on this question will be a major object of future work; this work can be undertaken hopefully now that the benzylcarbonato method affords a means of obtaining almost any peptide which may be desired.

From still another point of view, it has been possible to gain an insight into the structural and electro-chemical conditions which regulate the enzymic hydrolysis of peptides, namely, by experiments concerning the transformation of proteins into non-nitrogenous compounds. Hitherto, it has been thought that this transformation could only take place by way of the individual amino-acids themselves, which were supposed to undergo dehydrogenation and subsequent hydrolytic loss of nitrogen with formation of a ketonic acid.

At the time when we began experiments bearing on this point, no enzyme had been discovered which was capable of dehydrogenating amino-acids. For reasons which need not be discussed here, the idea occurred to us that such a dehydrogenation might be accomplished at the peptide stage. In order to test this hypothesis, a number of unsaturated di- and tri-peptides were synthesised and a search was made for an enzyme which might be capable of hydrolysing these compounds. An enzyme was in fact obtained from kidney[9] which attacked glycyldehydrophenylalanine with the production of glycine, phenylpyruvic acid and ammonia; the same enzyme also attacked glycyldehydroalanine with analogous results:

$$C_6H_5.CH:C(NH.CO.CH_2.NH_2).COOH \longrightarrow CH_2.NH_2.COOH + C_6H_5.CH_2.CO.COOH + NH_3$$

Glycyldehydrophenylalanine is completely resistant towards dipeptidases of plant and animal origin, amino- and carboxy-polypeptidase, trypsin and pepsin. On the other hand, the kidney enzyme is quite unable to attack glycylphenylalanine. It is clear therefore that the kidney enzyme is no ordinary dipeptidase but is indeed specifically adapted to the hydrolysis of unsaturated peptides.

The fact that glycylphenylalanine and glycyldehydrophenylalanine, two peptides which differ only by two hydrogen atoms, should require distinct enzymes for their hydrolysis, is of great importance in relation to the conditions of action of the various peptidases; it indicates that a compound may possess all the characteristics (a normal peptide linkage adjacent to free amino and carboxyl groups) hitherto regarded as essential to a substrate for dipeptidase and may still fail to be hydrolysed by this enzyme.

The existence and properties of the kidney dehydrodipeptidase have also important physiological implications, since they demonstrate a possible mechanism of deamination of protein degradation products in the body; moreover, the process involves the simultaneous formation in the kidney of keto-acids and ammonia, which are well known to occur in the urine in considerable quantities under certain conditions. It appears that the kidney, through its possession of this enzyme, may play a definite part in protein metabolism, particularly if we may assume that unsaturated peptides or related compounds of unsaturated amino-acids are produced in the course of renal metabolism. The likelihood of the latter assumption is indicated by the work of Krebs[10] who has shown that the kidney is capable of dehydrogenating amino-acids and peptides; in these experiments, however, the action of the kidney was not confined to the naturally occurring amino-acids but extended to their optical enantiomorphs, and it is therefore too early to say whether the results are of true biological significance.

Up to the present point, we have been dealing with the synthesis of new peptides and their behaviour towards enzymes. We must now pass on to consider the various conclusions, which experiments of this type enable us to draw, concerning the structure of the natural proteins themselves. This matter can best be exemplified by a consideration of the position occupied by proline in the natural proteins in the light of the behaviour of synthetic proline peptides of known structure[11].

The process of enzymic hydrolysis of a protein must be pictured as the successive scission of peptide linkages; this being so, it is natural to assume that every such scission will involve the liberation of an amino and a carboxyl group. The carboxyl groups liberated during digestion can be readily determined by titration in alcoholic solution by the method of Willstätter and Waldschmidt-Leitz, and the amino groups by the method of van Slyke. The course of enzymic digestion of many proteins has been followed with the aid of these methods and it has invariably been found that amino and carboxyl groups are liberated in equivalent amounts; in spite of the fact therefore that various authors, for example, Emil Fischer himself, have discussed at different times the possible occurrence of other than normal peptide linkages in proteins, no analytical evidence of the existence of such other linkages has been obtained, and the liberation of amino and carboxyl groups in equivalent amounts has indeed been taken as a criterion of true proteolysis.

Now we have already discussed two synthetic proline peptides, glycyl- and alanyl-proline, which are peculiar in that they are hydrolysed by amino-polypeptidase but not by dipeptidase; moreover, the hydrolysis of such a peptide, when it does occur, will give rise to liberation of a free carboxyl group but not of an amino group; in this case, therefore, the accepted rule of equivalent liberation of amino and carboxyl groups evidently does not apply. This fact can be utilised to throw light upon the mode of combination of proline and hydroxyproline in gelatin.

Proline can clearly occupy three distinct positions in the peptide chain of gelatin: (1) it may be attached through its carboxyl group to the amino end of the chain; (2) it may be attached through its imino group to the carboxyl end; (3) it may lie inside the chain, and be linked through its carboxyl and imino groups. The second and third of these possibilities involve the existence of linkages similar to that of glycylproline, and it is therefore possible, by comparing the action of proteolytic enzymes on gelatin and glycylproline, to decide whether this type of linkage is indeed present in gelatin or whether the proline is combined in the protein molecule entirely through its carboxyl group.

In order to test this question, gelatin has been submitted to digestion with trypsin followed by intestinal peptidase. Tryptic digestion causes rapid and equivalent increases in free amino and carboxyl groups whilst the peptidases cause a predominant increase in free carboxyl. Reference to the results obtained in the enzymic hydrolysis of the proline peptides will make it clear, therefore, that a large part at any rate of the proline (and perhaps also of the hydroxyproline) of gelatin must be combined through its imino group.

These experiments provide an example of a protein digestion in which free amino and carboxyl groups are not liberated in equivalent amounts; such equivalence can therefore no longer be regarded as an essential characteristic of proteolysis. Furthermore, they show in a convincing manner the importance of the individual constituent amino-acids in determining the behaviour of a protein towards enzymes; owing to the structure of proline the peptide chain is heterogeneous at those positions where proline is linked through its imino group, and this heterogeneity forces the process of enzymic degradation of the protein to follow a certain course.

We may now pass from the amino-acids, peptides and peptidases to a brief consideration of the enzymic degradation of complete proteins. Very little is known of the enzymes (proteinases) which are able to attack proteins of high molecular weight, but the action of these enzymes is of great importance; not only are they responsible for the first stages of the digestion of all protein taken in the food, but also there are industrial processes of the first importance which depend on the enzymic digestion of proteins.

A serious difficulty in the investigation of proteinase action is that these enzymes often have to work in heterogeneous systems, since the substrate may be largely undissolved, and hence the simple rules of mass action cannot be applied; the variable magnitude of the surface of the protein exposed to enzymic attack complicates the situation so that the curves representing the course of action of proteinases on undissolved proteins are not susceptible of simple interpretation.

In the case of gelatin the problem can be simplified to some extent by using the protein in the form of films of uniform size and thickness, so that the surface of protein remains practically constant during digestion; moreover, the course of the digestion can be conveniently followed optically if a black insoluble substance be previously distributed evenly through the gelatin, so that it gradually passes into the aqueous phase as digestion proceeds. With the aid of this method it has been found that the course of digestion of gelatin is represented by the simple formula: $x = kt\sqrt{E}$, where x = digestion (per cent); k = constant, t = time, E = enzyme concentration (per cent).

This formula is valid during the whole of the process of digestion, and for concentrations of enzyme varying from 0·0001 to 0·1 per cent and more. Thus apart from variations in the surface exposed, it may be stated that the rate of digestion of a protein is proportional to the time and to the square root of the enzyme concentration, but is not affected by the total amount of enzyme or of protein[12].

The same rule applies to the digestion of fibrous collagen, at least during the first third of the digestion period, provided that precautions are taken to prevent the inactivation of the enzyme. The validity of the formula in the case of collagen is at first sight surprising, since it might be expected that the fibres would become thinner during the digestion and that the surface would then be altered. The only explanation of the constancy of the rate of digestion actually observed seems to be that digestion of the collagen fibres proceeds only from their ends. That this is indeed the case is shown by the fact that the rate of digestion of true skin is proportional to the area of the external surface in which the ends of the collagen fibres lie.

The key to present-day and future protein chemistry lies in the development of new synthetic methods, and this is the justification for the expenditure of so much time and labour on the improvement of such methods. In these lectures I have described technical advances made during the last few years in my laboratory, which have thrown some new light on the specificity of the proteolytic enzymes, at the same time extending our knowledge of normal and pathological protein metabolism. With the aid of the combined efforts of enzyme chemistry and organic synthesis, we may reasonably hope that these advances will be continued.

University and Educational Intelligence

CAMBRIDGE.—In his will, Mr. F. E. Elmore, who died last year, bequeathed the income of a trust fund for the provision of scholarships for medical research to male post-graduates of British or Colonial birth at the University of Cambridge.

Prof. A. C. Seward has announced the gift of 6,000 sheets of mounted and named British plants to the University Herbarium by Mr. J. E. Little, of Hitchin.

A University lecturer and a University demonstrator in physics will be appointed shortly. Further information can be obtained from Mr. H. Thirkill, Clare College.

The Buildings Syndicate recommends that the plans prepared by Mr. Lodge for an extension to the Botany School be approved and that the tender of £13,652 from J. Parnell and Sons for the work be accepted.

C. F. A. Pantin, of Trinity College, has been approved for the degree of Sc.D.

EDINBURGH.—Prof. Ivan de Burgh Daly, professor of physiology in the University of Birmingham, has been appointed professor of physiology in succession to Sir Edward Sharpey Schafer, who will retire on September 30.

LONDON.—The following grants have been made to the University, payment being spread over a period of years: Haberdashers' Company, £500; Saddlers' Company, 500 guineas; and Apothecaries' Society, £500. A small donation has also been made by the Glass-sellers' Company, which expressed its desire to be associated with the Bloomsbury scheme. These benefactions will be applied towards meeting the cost of the new Ceremonial Hall to be erected on the University's site in Bloomsbury.

IT is announced by the New York correspondent of the *Times* that Dr. James B. Conant, Sheldon Emery professor of organic chemistry at Harvard University, has been made president of the University in succession to Dr. A. Lawrence Lowell, who has resigned.

THE report of the University of Leeds on the session 1931–32 shows that the number of students as a whole and in the various faculties was well maintained despite its having been a time of severe retrenchments of expenditure. Of the 1,520 full-time students (including 367 women) 1,197 were from Yorkshire homes, 24 from other English counties, 54 from India, 12 from Wales, 12 from Egypt and 34 from other countries. Their distribution by faculties was: arts 45 per cent, medicine 24, pure science 14, technology (engineering, mining, coal, textiles, dyeing and leather industries) 14, agriculture 3. Of the students who graduated in 1931, not more than eight per cent were known to be unemployed by December of that year but "there are signs during the current year that greater difficulties than formerly may be experienced in placing our graduates". In a separate pamphlet is given a list of 215 publications (chiefly in science and technology) by members of the University, and abstracts of theses (also chiefly in science and technology) accepted for higher degrees. In the course of the year, the Clothworkers'

Company renewed its grant of £3,000 a year for research in textiles, in addition to the £3,000 for the Textile Industries and Colour Chemistry Departments. Quite recently the University authorities have announced that a discovery made in the Textiles Department by a Swedish investigator, Mr. Hellberg, of a new type of wool pack, is likely to obviate losses of many thousands of pounds suffered annually through contamination of wool packed for shipment. An outstanding event of the year was the institution of a new chair, of the philosophy and history of religion, for which an endowment of £20,000 was provided under the will of Mrs. Emily Fawcett.

Calendar of Nature Topics

Indian Hot Weather

The year in India is divided into three seasons: the cold weather, the hot weather, and the monsoon. The cold is relative, for even in January the average temperature over the whole Indian land area is 67° F., but the hot weather, which begins in April and continues into June, is extreme. The climax comes in May, when the average of the twenty-four hours exceeds 90° F. over the greater part of the interior, and the day temperature regularly exceeds 100° F. over half the country. There is a considerable daily variation, but in many places the thermometer remains above 80° F. throughout the night. The air is dry and dusty, and the ground is baked hard. Early in June, before the monsoon breaks, the climate is even more oppressive, for the heat continues unabated while the air becomes moister and more sultry. The first steady rains bring an appreciable fall of temperature and are eagerly awaited.

An Experiment in Direction Finding

On May 15, 1900, there began one of the most instructive of experiments on the locality sense of birds. "Twelve noddies and twelve sooties [terns belonging to the species *Sterna stolida* and *S. fuliginosa*] were captured on Bird Key on May 15. The next day they were sent to Key West and, on May 17, put aboard a freight steamer for Galveston. The cages were hooded and, except at feeding time, the birds had no chance of seeing anything which would give them their bearings. On the night of May 20 two birds (both noddies) were released but neither returned to their nests.

"On May 21, at 8 a.m., four noddies and six sooties were released; at 7 p.m. two more noddies were set free under extremely difficult conditions, as a heavy rain began falling that night which continued without interruption all the next day. Of the twelve released five noddies and five sooties returned.

"During the morning of May 23 the remaining birds, four noddies and six sooties, were fed and freed in Galveston Harbor, 855 miles west of Bird Key. Of these ten, one noddy and two sooties reached their nests."

With reference to this last test, the experimenters, Drs. J. B. Watson and K. S. Lashley, pointed out that the failure of so many birds to return was not surprising in view of the numbers of hawks frequenting the Texas shore, and the tired condition of the terns after their eight days' confinement.

Conclusions regarding Homing Sense of Terns

The experiments, of which one has been described above, took place in the Gulf of Mexico, where regularly towards the end of April, a great colony of noddy and sooty terns arrives at Bird Key, one of the islands in the Tortugas group. The experimenters regarded the results of their many tests of the homing sense of the terns as showing that where care was taken to keep the captured birds in good condition before they were released, they could find their way back to the nesting colony over almost any distance up to a thousand miles, and this although the region of the return journey over the Gulf of Mexico presented no landmark to serve as a guide. It has been pointed out that the ability of these untrained birds to find their way home over a thousand miles through haze, storm and darkness, and over an unknown sea, is all the more remarkable when it is compared with the record long-distance flight of a homing pigeon, 1010 miles; for pigeons are selected and go through an intensive training to accustom them to the landmarks of the region they must traverse on their return journey.

Mayflies and Man

The disappearance of mayflies (*Ephemera* spp.) from many parts of England where formerly they appeared in vast numbers is well known. How far this is due, indirectly, to human agency is not yet clear, but it is likely that operations leading to rapid drainage of adjoining country with consequent flushing of watercourses are among the factors involved. A current too fast to allow of an adequate deposit of fine sand, 0·25 mm.–0·05 mm., markedly affects the normal development of eggs of *Ephemera danica* (Percival and Whitehead, 1926). Moreover, ephemerid nymphs in general need a substratum of a well-defined sort composed of particles 1 mm.–0·25 mm. in diameter in order to thrive. Such a bottom is easily disturbed by sudden rushes of flood water.

The influence of man both by land clearance and by the introduction of new species among the native fauna has been found to have very marked results on the New Zealand Ephemeroptera. Bush felling near watercourses has altered the conditions in streams so that in summer the beds dry up and nymphs and egg masses shrivel. The great increase in rapidity of the run-off from cleared land after freshets results in maimed insects pounded by current-borne stones and debris. Removal by felling of shelter for subimagines and imagines leaves them an easy prey to birds like the pied fantail, the ground lark and the introduced chaffinch. Of the food of the introduced trout, 9 per cent consists of various Ephemeroptera in the Wellington district. Between two and three hundred nymphs of *Coloburiscus humeralis* were found in the stomach of an Atlantic salmon—another introduced fish—from the Waiau River (Phillips, 1931).

A converse case has been noticed in the Yorkshire Nidd, a rapid stream where, owing to the impounding of water in reservoirs higher up the river, flooding has been very much reduced. In consequence, a certain amount of fine deposit occurs among the larger stones, affording shelter to many nymphs of *E. danica* (4 per 4 sq. dec.), a number sufficient to produce a considerable crop of adults annually (Percival and Whitehead).

Societies and Academies

LONDON

Physical Society, March 17. H. A. NANCARROW: A method for the determination of the thermal conductivities of rocks. The rock specimens are turned as circular cylinders of diameter 5 cm. and height 2 cm., and are bisected by a cut made perpendicular to the base along one diameter. The top of the cylinder is heated and the temperature-gradient in the specimen is measured by means of thermocouples held in a mica holder inserted in the cut. The temperature-distribution and heat flow in the specimen are each represented by a series containing Bessel and hyperbolic functions. Constants involved in the arguments of these functions are dependent upon the loss of heat from the hot surfaces exposed to the air in the apparatus. E. E. WRIGHT: A note on the Kerr cell. The distortion due to the curvature of the (light, voltage) characteristic of a Kerr cell is discussed, and an expression giving the amplitudes of the Fourier components of the light-variation due to a pure alternating potential applied to the cell is obtained. Sets of curves showing the variation of percentage of second and third harmonic with bias and with amplitude of the applied alternating potential are given. The working conditions for minimum distortion obtained from these curves agree with those used in practice. The late A. C. G. BEACH: An experiment bearing on Talbot's bands. The form of diffraction pattern observed in a spectroscope when a point of light is produced on the slit of the collimator, and an aperture in which the upper or lower half is covered with a retarding plate is between the collimator and telescope, is discussed and the bands so produced are used to explain Talbot's bands.

Society of Public Analysts, April 5. H. G. REES: Notes on the iron and copper in liver and liver extracts. The amounts of iron and copper previously recorded for the livers and liver extracts of various animals are too low; these metals are very incompletely extracted by water. In the author's experiments the proportion of iron was somewhat higher, whilst the copper was very much lower than the figures given by Meyer and Eggert. G. W. MONIER-WILLIAMS: Determination of the freezing-point of milk. The three main factors influencing the determination are: super-cooling; the water-value of the container, thermometer, bulb and stirrer; and the heat-exchange with the surrounding medium. With the new type of apparatus devised by the author, the supercooling correction can be determined with a fair degree of accuracy, the final temperature remains constant for several minutes, and excellent heat insulation is secured by the casing of compressed cork.

DUBLIN

Royal Irish Academy, Feb. 13. COMMON and CAIRNS: The colonisation of a disused millpond at Hillsborough, Co. Down. An account of observations made on the ecology of a disused millpond over a period of three years. The pond has become largely silted up during the past twenty years. The phases in the progressive colonisation of the pond are very clearly defined. The submerged phase, at first dominated by *Potamogeton*, is now dominated by *Chara*. The main emergent phase is an Equisetetum but this rôle is assumed at one place by *Caricetum* from which *Equisetetum* is absent. Invasion by *Carex* transforms the Equisetetum into sedge meadow: this is succeeded by *Salicetum*. The plant succession is regarded as a colonisation of a silt slope and not as a true hydrosere.

PARIS

Academy of Sciences, March 27 (*C.R.*, **196**, 881–972). EMILE BOREL: An elementary problem of probabilities and the quasi periodicity of certain arithmetical phenomena. R. FOSSE, P. DE GRAEVE and P. E. THOMAS: The rôle of allantoic acid in the higher plants. Summary of the methods of identification and determination of allantoic acid in plants. Also a study of the changes in the proportions of this acid during germination. J. DELSARTE: On a ds^2 with non-static axial symmetry and some connected problems. GEORGES BOURION: A class of Taylor's series. JULIUS WOLFF: The extension of a theorem of Warschawski on conformal representation. MICHEL LUNTZ and PAUL SCHWARZ: A particular case of the movement set up in a viscous fluid by the rotation of a cylinder. FLORIN VASILESCO: Movement with a wake, in three dimensions, of a solid body in a fluid. R. D'ADHÉMAR: The equations of the gyroscopic movement of stable projectiles. JEAN MARIANI: Quantic mechanics and the theory of finite and continuous groups of Sophus Lie. G. LEMAÎTRE: Spherical condensations in an expanding universe. E. HOCHARD: Maintained oscillations. Some applications of a photoelectric cell for producing maintained electrical oscillations of determined period. E. GAMBETTA: The measurement of small luminous fluxes by means of the photoelectric cell. HENRI ABRAHAM: The definition of the magnetic field. A comparison of the modes of calculation of Maxwell and of J. J. Thomson: the latter is easier in its practical applications. P. LAINÉ: The magnetic properties of liquid ozone. Magnetic measurements on ozonised oxygen having given discordant results, experiments with liquid ozone are now described. From the results of these it is deduced that ozone is paramagnetic and has a susceptibility independent of the temperature. CH. BERTIN: The accuracy attainable in radiogoniometry and the use of the *droite-radio*. F. CROZE: The aberrations of coma of light pencils of large inclination. NY TSI-ZE and CHOONG SHIN-PIAW: The absorption of light by ozone between the wave-lengths 3050 A. and 2150 A. A table of coefficients of absorption for 194 wave-lengths. PARISELLE: A curious case of change of sign of the rotatory power and of mutarotation. A study of the properties of the complex compound obtained by dissolving aluminium hydroxide in tartaric acid. P. JACQUET: The adsorption of colloids by metallic surfaces and its influence on the adherence of electrolytic deposits. The colloids studied fall into two groups, those clearly affecting the adherence of the deposit, such as proteins and peptones, and those without action, such as gums and dextrin. MAURICE CURIE and S. TAKVORIAN: The radioactivity of a neodymium-samarium fractionation. The element 61. Starting with a mixture of 5 kilograms of neodymium and samarium (from Indian monazite) the authors find that neodymium and lanthanum show no radioactivity. Samarium emits a very absorbable radiation, apparently not due to element 61, but the intermediate fractions give a more penetrating radiation probably due to element 61. A. GIRARD and G. CHAUDRON: Crystalline systems of microcrystallised ferric oxides. Results of X-ray analysis and thermomagnetic analysis of ferric oxide prepared by eight methods. P. MONTAGNE: The graphical resolution of problems of homogeneous chemical equilibrium between three constituents. G. CHAMPETIER: The action of solutions of orthophosphoric acid on ordinary cellulose. The existence of the addition compound $3C_6H_{10}O_5.H_3PO_4$ is proved by Schreinemakers' method: washing with water regenerates cellulose without mercerisation. E. CARRIÈRE and R. LIAUTÉ: The estimation of sulphurous acid and alkaline sulphites by potassium permanganate. A. SANFOURCHE: The relations between the properties and constitution of tricalcium phosphate. MME. G. ALLARD: The refractometric determination of organic acids. MLLES. H. VAN RISSEGHEM and B. GREDY and M. L. PIAUX: The ethylene linkage. Study of some linear or branched hexenes. Raman spectra of eight hexenes. V. KUNZL and J. KÖPPEL: A precision method for measuring the constants of crystalline networks. PAUL GAUBERT: The influence of foreign substances in the state of solid solution on the domain of stability of crystals. J. BARTHOUX: The Siwilak and the recent volcanic rocks in Afghanistan. ANDRÉ LENOBLE: The schisto-quartzo-limestone series in the centre of Madagascar. F. BLONDEL: The distribution of the richness of metalliferous deposits. L. TUWIM: First results obtained in a new cosmic ray observatory. J. CHAZE: The presence of anthocyanin pigments or oxyflavone compounds in the aleurone grains of certain Gramineæ. MARC SIMONET: The behaviour of the chromosomes in some complex hybrids of *Iris*. MLLE. PANCA EFTIMIU: The presence of a fungus in *Bucegia Romanica*. RAYMOND-HAMET: Digitalin compounds do not prevent cardiac syncope produced by adrenaline when it is made to act during the stimulation of the vagus. MME. HUFNAGEL and MARCEL JOLY: The different behaviour with regard to X-rays of the fly and butterfly in the course of their metamorphosis. FRED VLÈS, MLLES. ANNA GROSSMANN and MADELEINE GEX: The electromotive forces developed by man in contact with a metallic conductor. JEAN CAMINOPETROS and B. CONTOS: The intradermal reaction with pustular fever. CHARLES LAPP: The rotatory power of quinine salts in aqueous solution. If the pH is brought to about 5·5 with chlorophenol red as indicator, quinine can be determined optically whatever may be the acid with which it is combined.

MELBOURNE

Royal Society of Victoria, Dec. 8. R. T. PATTON: Ecological studies in Victoria. (1) The Cheltenham flora. The association is closely allied to the heaths of the northern hemisphere, both ecologically and taxonomically, a constituent family being Epacridaceæ. The composition of the association is very rich, consisting of members of many diverse families. All, however, possess an ericoid type of leaf. The physiognomy is related to both the climatic and the soil conditions. The soil is very sandy and belongs to the podsol type but it exists under climatic conditions widely different from those of the podsol areas of Europe. The association is typically xerophytic but the morphology of the ericoid leaves does not show any consistent adaptation to the dry period of the year. E. BROADHURST and J. D. CAMPBELL: The geology and petrology of the Mount Leinster district, north-east Victoria. The oldest rocks are Upper Ordovician sediments which have been converted to schists and quartzites by an intrusion of granodiorite, which itself becomes gneissic at its border. A granite porphyry is intruded into the granodiorite. A younger series of alkaline rocks consist of trachytes and trachyte tuffs, into which a soda syenite has been intruded. At the contact with the syenite, the biotite in granodiorite has inverted to hornblende and finally to augite, and quartz has been dissolved and orthoclase has been deposited in its place. A fault on Mount Leinster has brought the granodiorite and trachyte into contact, and a series of specimens across the shear zone, showing granulation, is described. The felspars in the syenite, particularly in some of the dykes, have a peculiar interpenetrating structure. FREDERICK CHAPMAN: Some Palæozoic fossils from Victoria. The following are described and figured: A species of Silurian seaweed, *Bythotrephis divaricata*, first described from the Wenlock of England, and occurring near Walhalla and at Studley Park; two new species of foraminifera from the Silurian of Lilydale and Mitcham, *Hemigordius lilydalensis* and *Trochammina bursaria*, both of which genera have hitherto been unknown from rocks older than the Carboniferous; and a new species of brachiopod, *Orbiculoidea antipodum* from the Lower Ordovician of Lancefield (Darriwilian Series), related to *O. perrugata* from the Caradoc beds of Ireland, described by McCoy in 1846.

VIENNA

Academy of Sciences, Jan. 12. JOSEF SCHAFFER: Differences in the tissue structure of homologous organs (prepuce glands) in mice and rats. In arrangement and external form these glands, although of different size, are very similar in the two animals. As regards fine structure and type of secretion, however, such marked differences appear that the glands must be regarded as of quite different types. In the rat, the secretion is mainly albuminous, and in the mouse purely fatty in character. KARL MAYR: Definite integrals with Bessel's functions. The investigations begun in the author's "Bestimmte Integrale und hypergeometrische Functionen" are continued and applied to the generalisation of an integral examined by Struve and Rayleigh. KARL KLEMENZ: Investigations on Archimedean bodies in spaces of several dimensions. It was found earlier that, in space of four dimensions, only two of these bodies are possible, when congruence of the angles and equality of the edges are required. Extension of the investigations to spaces of more than four dimensions shows that, in such spaces, polytopes with congruent angles and equal edges no longer exist. FRIEDA KANN: Influence of temperature on the stages of growth of *Dixippus* (*Carausius*) *morosus* Br. et Redt. ROMAN J. WOJTUSIAK: Antagonistic action of ultra-violet rays on the phototaxy of *Daphnia magna* Straus. Like blue and violet light, light rich in ultra-violet rays repels daphnids; like darkness, light poor in ultra-violet rays exerts no action, and like red and yellow light, white light free from ultra-violet components has an attracting effect. TOSHIHIKO YAMANÔUTI: Growth measurements on *Sphodromantis bioculata* Burm. (5) Determination of the absolute increases in the size and number of the facets. HANS HORNICH. (1) Construction of integrals of the first genus on special transcendent Riemann surfaces.

Jan. 19. **Martin Kofler**: Distribution of precipitations according to their diurnal periods. **Friedrich Hernegger**: Sensitive methods for the detection of uranium in spring waters and deposits. For determining the traces of uranium present in radium-containing springs, the chemical method with potassium ferrocyanide and methods based on fluorescence have been investigated. **Josef Hoffmann**: Alkali- and barium-silver chlorides. Huantajayite and similar sodium-silver chlorides artificially prepared remain unchanged in sunlight, but if the content of silver chloride is increased, the compounds become sensitive to light. The coloration of huantajayite under radium irradiation is similar to that of natural rock-salt, but the irradiated pressed mineral exhibits no colour changes. The colours of potassium-, barium-, and cæsium-silver chlorides are considered. **Rudolf Toth**: Geology of the "Schneeberg" region. **Viktor Pietschmann**: Three new fish species (Cyprinides) from Asia Minor. These species are: *Acanthorutilus handlirschi* nov. spec., *Varicorhinus pestai* nov. spec., and *Schizothorax prophylax* nov. spec.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Monday, May 15

Royal Geographical Society, at 8.30.—Prof. Giotto Dainelli (and others): "The Geographical Work of H.R.H. the Late Duke of the Abruzzi".

Tuesday, May 16

British Science Guild, at 4.30—(Research and Development Lecture in the Carpenters' Hall, Throgmorton Avenue, E.C.2.)—Sir Harold Carpenter: "Metals in the Service of Human Life and Industry".

Royal Photographic Society.—Dr. G. M. B. Dobson: "The Significance of Ozone in the Atmosphere and its Measurement by Photographic and Photoelectric Methods".

Wednesday, May 17

London School of Hygiene and Tropical Medicine, at 3.15.—Dr. R. H. Crowley: "Child Guidance".*

Royal Society of Arts, at 4.30.—Prof. Maiuri (director of excavations at Pompeii and Herculaneum): "The Recent Excavations of Herculaneum and Pompeii".

Folk-Lore Society, at 8—(at University College, Gower Street, W.C.1.)—Sir Reginald F. Johnston: "Tree Worship and Holy Wells in China".

Friday, May 19

Royal Society of Arts, at 4.30.—Sir Arnold T. Wilson: "The Suez and the Panama Canals—a Comparison".

Bedson Club, at 6.30—(in the Chemistry Theatre, Armstrong College, Newcastle-upon-Tyne).—Prof. A. Harden: "The Chemistry of Fermentation".

Royal Institution, at 9.—Dr. V. M. Slipher: "Planet Studies at the Lowell Observatory".

Third Glass Convention, May 18–20. To be held at Buxton.

Research in Central Asia

HOWEVER admirable in theory may be the ideal that science should transcend the limitations of nationality, it has to be recognised that there are fields of scientific research in which, in the circumstances of the present day, this is neither possible nor perhaps in every way desirable. The intensity of national self-consciousness, which has been fostered by various influences during the last fourteen or fifteen years, has invaded the field of science, and restricts the activities of research in those branches of study which depend for their material on the exploration, or as the nationalists would have it, the exploitation, of territory to which everywhere access is limited by national rights. Further, as a logical consequence, each nation claims, not necessarily without some show of justice, to determine the number and character of the specimens collected which shall be allowed to leave the country or shall be retained to enrich the national collections.

This intensification of national feeling is responsible for the increased stringency of regulations which once were at worst irksome, but now, at times, have become definitely obstructive or even prohibitive. The most recent and serious example of a more exigent regulation of scientific exploration—especially serious because of the wide range of scientific activities affected—is afforded by China. The strongly restrictive attitude of the Chinese authorities since 1928 towards scientific expeditions working within the boundaries of the Empire has imposed conditions upon the work of the Central Asiatic expedition of the American Museum of Natural History, which the Museum does not feel able to accept, and has brought to an end ten years of unprecedented contribution to scientific knowledge; and it has caused Sir Aurel Stein to withdraw from Turkistan, where his explorations had brought to light an unexpected wealth of evidence bearing upon the cultural history and geography of Central Asia.

It may be a not unreasonable view that the very success of these expeditions has led to their embarrassment. Dinosaur's eggs, for which collectors, according to the story given a world-wide circulation in the Press, were prepared to pay £100 each, six thousand manuscripts of early Buddhist and other writings, including texts translated by the Chinese Buddhist missionary and traveller of the seventh century, Hsüan-Tsang, and priceless painted silks, the earliest known, with many other finds of equal scientific, if less widely advertised, value when conveyed to America and England, may well have impressed upon the Chinese the idea that they were being deprived of historic treasures of untold worth. With this point of view, the European peoples, who are making every effort to prevent their own artistic and historic treasures from leaving their respective countries, may well sympathise. From the scientific point of view, it is possible to hold that a specimen, whether appertaining to the natural kingdom or to the culture of man, is best preserved for study within striking distance of its natural environment, provided that it is then reasonably accessible to students and that adequate facilities are afforded for its examination.

While the claims of science and politics are thus seen to coincide in the demands of regional studies and historic association, too great insistence upon them may prove detrimental to the advancement of knowledge. It may check exploration. Expeditions on the scale now considered necessary for regional exploration in an area like Central Asia are expensive undertakings, and can be initiated and carried out only by, or through, a great organisation, such, for example, as one of the more important museums. Apart from finance, only an organisation such as this can hope to bring together and hold the numerous body of experts in the various branches of science—geology, geography, climatology, zoology, botany, palæontology, anthropology and archæology—which is considered essential if full advantage is to be taken of the opportunity afforded by such an expedition for joint study of related problems in the field. It is not unnatural, however, that in the conduct of an expedition on this scale the organising body should expect to be allowed a certain freedom of initiative to enable it to deal with unexpected developments in the course of the investigation, as new vistas are opened up by exploration ; and that it should look for a return in the shape of additions to its collections. If in both these directions the regulations laid down by the national authorities are unduly restrictive, exploration presents no adequate inducement and science is deprived of material *ex hypothesi* essential to its advancement.

Much of this may seem obvious. Its recapitulation will serve to recall conditions which have been found obstructive to research in more countries than one. In China they have brought about a deadlock in the two instances mentioned, notwithstanding the expressed desire of the Chinese to co-operate in scientific exploration. In view of the importance of China as a future field of research, it is of the utmost moment that every effort should be made to bring about a more favourable situation in order to enable science to reap the fullest advantage from Chinese readiness to join in promoting the exploration of the vast store of scientific material in that Empire.

China is the gateway of Central Asiatic research. Not only does the vast area of Chinese Turkistan and Inner Mongolia lie under her jurisdiction ; but also through China access may be gained to Outer Mongolia, Russian Turkistan, and Tibet along ways which have been trodden by one race after another for thousands of years. The achievement of the American Central Asiatic expedition in Mongolia in geology, in palæontology, in palæobotany and, to a lesser degree, in archæology has demonstrated the importance of that area as a great and almost unexplored source of evidence for the history of the Asiatic continent and as a centre of dispersal of many forms of animal life. The sense of this importance is borne upon us, not so much by the evidence that has been collected during the past ten years, great as this is in the mass, as by the array of further problems in the various sciences which that evidence has suggested, but of which the investigation is now suspended. It may well be, as one of the members of the expedition hopes, that eventually further exploration in this area will bring to light evidence of *Proanthropus*, the precursor of man, for whom research has waited so long. The results of Sven Hedin's expedition in Chinese Turkistan during the last six years, an expedition planned on similarly comprehensive lines to those of the American expedition to Mongolia, also point to the importance for scientific research of this area.

The material which has already been obtained, and which it is hoped to obtain from further exploration, is not merely of interest for its bearing on strictly local problems, or even of problems within the bounds of Asia. In Mongolia, for example, the alternation of desiccation with the growth of vegetation, for which there is geological evidence, and in later ages the variations in the occupation by man of areas now desert, may well help to solve, by the light they throw on climatic oscillation, problems relating to early man in East Africa and the relation of conditions in both Africa and Central Asia to the glaciations and associated cultural material of

Europe. Again, studies in the palæobotany of Mongolia are already throwing light on the distribution of the flora in tertiary times not only of the extreme east of Asia, but also of America.

Such problems as these are of world-wide interest, and should be attacked in no particularist spirit. Central Asia, indeed, has attracted scientific exploration from many sources. Within the present century, Russian, American, German, French, Italian, Swedish and British expeditions have contributed to the study of its problems in geography, geology, palæontology, zoology, archæology and other related sciences. Japan is interested in these researches in view of their bearing on her own problems. Nor must it be forgotten that the palæontological researches of the Geological Survey of China, which led to the first discovery of evidence of Peking man *in situ*, were initiated by Swedish money and with a Swedish personnel. Since 1928, China herself has had a body, now known as the Commission for the Preservation of Ancient Objects, which concerns itself with the scientific exploration of the Empire's natural and cultural history. Although it has not undertaken scientific exploration independently, it has taken steps to ensure that Chinese investigators should be included in the personnel of foreign expeditions which have received the sanction of the Chinese authorities.

In view of the magnitude of the undertaking, the importance to science of the results, and of past history, the exploration of Central Asia—and with this must be included a great part of China proper—seems pre-eminently a matter for international co-operation. On political and other grounds, it is clear that the task is too great for China unaided, at any rate for the moment; while co-operation between China and individual expeditions conducted by foreigners may not, at the best, be entirely satisfactory, failing any international board of arbitration in scientific matters, such as might perhaps have been in other circumstances a function of the International Committee on Intellectual Co-operation.

Of the various possible methods of dealing with the situation, the most practicable is, perhaps, an International Institute for Central Asiatic research. Such a proposal, indeed, has been put forward by Dr. Roy Chapman Andrews, leader of the American expedition to Mongolia, in the recently published first volume of the final reports of the Expedition. Dr. Andrews, however, has now abandoned this proposal in view of the differences which have arisen with the Chinese authorities and have brought his explorations to a close.

There is no reason why this should be final. Whereas, however, Dr. Andrews intended that the headquarters of the institute should be in New York, with field headquarters in Peking, it is probable that, if the full co-operation of the Chinese is to be secured, the Institute should be situated in China. Each of the western nations participating in the work of the Institute should have a resident representative, advised and supported by a committee in his own country, acting as a medium of communication between the general body of scientific workers of that country and the Institute, as well as being responsible for finance. The countries territorially interested, China, Mongolia, the Russian Soviets and Tibet, would also be represented in the Institute, although the extent to which they should participate in its actual work would, perhaps, be difficult to suggest before the proposal begins to take more definite shape. Full co-operation would seem the ideal, but might be difficult of arrangement. Such an Institute should be in a position to formulate and organise schemes of research upon a settled plan, with economy of money and effort and, it is hoped, with an absence of friction, whether relating to the objects and details of exploration, or the disposal of its material results to the best advantage of scientific studies.

Science and Culture

The Anatomy of Modern Science: an Introduction to the Scientific Philosophy of To-day. By Bernhard Bavink. Translated from the fourth German edition, with Additional Notes and Bibliography for English Readers, by H. Stafford Hatfield. Pp. xiii+683. (London: G. Bell and Sons, Ltd., 1932.) 21*s.* net.

THE imperative need of supplementing the specialist's knowledge by a more comprehensive consideration of the problems of science, without which the former is little more than a kind of scientific trade, is increasingly felt and is illustrated by the number of books which in recent years have attempted to interpret to a wide public the results of scientific research, and to correlate from a general and philosophical point of view the significance of these results and of the problems still unsolved. Such an exposition calls for exceptional gifts, and though the attempt has been freely made in England, there still appears to be an outstanding need for a real synthesis on broad philosophical lines of the inexhaustible material of natural science.

The outstanding success of Bavink's "Anatomy of Modern Science" in Germany may be attributed to his presentation in the first place of the results of science out of which the philosophical questions have been allowed to develop naturally, and few books have raised more fairly the problems of the relations of science and philosophy or given a more sincere, impartial or patient interpretation of human values. If only for its brief remarks on the problems of rationalisation and the mechanisation of life, the book should be welcomed by all who, from the scientific side, are attempting to see life steadily and to see it whole.

A grave danger of the present time is that man's knowledge of physical laws far exceeds his knowledge of the science of man. On this point Bavink cites some impressive evidence. A convinced believer that the biological sciences are capable of yielding genuine knowledge, he emphasises the importance of scientific biological knowledge for the discussion of cultural questions. He regards the neglect of science in the curricula of our higher educational institutions as responsible for the inadequate conceptions of the driving forces of history possessed by large sections of educated people. Those who confuse culture with literature and art cannot understand the biological conditioning of cultural achievement, and accordingly cannot draw the appropriate deductions.

Ignorance of the true causes of such processes results in our failure to perceive that many so-called social reforms are in fact anti-social, and, apart from perpetuating tainted and undesirable elements in our population, lead to opposition to the measures required to preserve racial health. This misdirection of moral and social effort is a serious factor in our present position, above all in the framework of democracy, and the danger of persistent degeneracy is too serious to be ignored. Bavink makes the trenchant comment that no civilisation has ever possessed the knowledge which we possess of the deeper causes of cultural processes and racial decline. The remarkable development of our physical technology gives us some idea of the possibilities in biotechnology when biology represents a science as advanced as physics or chemistry.

Here we touch on the ideal of fitness for a purpose for its own sake, an ideal which is behind the present-day urge for rationalisation and scientific administration, and in one of the most suggestive chapters of his book Bavink discusses the value of technology as a cultural field for itself, standing on an equality with art, science and religious ethics. This discussion is the more timely in view of the tendency to overstress the financial side in referring to the economy of technology.

In his presentation of these issues, Bavink brings us face to face with the problem of values. These concluding chapters are undoubtedly provocative, but they keep clearly in mind the question of preserving the values bequeathed to us by the past without exposing civilisation to unbearable hindrances. There is no hasty dogmatism but the realisation, taught by the historical perspective, that it is fundamentally wrong to believe we hold in our hands the absolute and final truth, the ultimate value in any category. As in the field of scientific knowledge of truth, there must be constant striving for truth, believing that such striving is not in vain, that æsthetic values, like scientific truths, have a significance independent of whether, where, and by whom they are grasped. Scientific workers and artists of the highest rank have often shared the same feeling that what was given to them to achieve was something that they laid hold of, and not really something they themselves produced.

Bavink concludes his exposition of scientific philosophy upon a note which irresistibly recalls General Smuts's presidential address in 1931 to the British Association. "Where the scientist and philosopher have to be silent, the artist, the poet and the prophet may still speak to us, indeed, this is their truest realm. What can no longer be stated in the ingenious phrases of human wisdom may still be brought home to the sensitive spirit by the language of religious inspiration, art, and above all music to such an extent that we may well be in doubt which may bring us nearest to the root of the matter."

It is a worthy close to a valuable work which gives us at once a comprehensive view of man's achievements in the physical world, as welcome for its pragmation and relation to the real problems of our society as for its consciousness of the spiritual and moral values among which science itself is rightly to be ranked.

R. B.

Stands Darwin Where He Did?

The Causes of Evolution. By Prof. J. B. S. Haldane. Pp. vii+235. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1932.) 7*s.* 6*d.* net.

ONCE again Prof. J. B. S. Haldane has produced a lively and stimulating book. Dealing with problems of general significance, it contains much to interest both the professional biologist and the layman. It is based on a course of lectures delivered at the Prifysgol Cymru, Aberystwyth, and entitled "A Re-examination of Darwinism". Although, as its new title implies, its scope is now somewhat larger than the original title of the lectures would suggest, yet the main purpose of the book is to examine the Darwinian hypothesis of natural selection as a cause of evolution in the light of modern experimental and theoretical work.

As we should expect, Prof. Haldane's discussion combines vigour with authority, and his text is full of new and illuminating material. His first chapter states the problem. He shows how, when the doctrine of evolution first gained general acceptance, it was combined, as Darwinism, with the explanatory idea of natural selection. Later the two became dissociated. Positive evidence for evolution accumulated and became more and more convincing. But at the same time the belief in natural selection, which was originally almost inseparable from the belief in evolution, has weakened—or at least, it has not gained support at anything like the same rate, so that, as Prof. Haldane writes, "a few biologists and many laymen regard it as more or less exploded". The reasons for this reaction are described.

The next two chapters, perhaps the most valuable in the book, deal with variation within a species, and with interspecific differences, in the light of recent genetical and cytological investigations. It is shown that

> "Interspecific differences are of the same nature as intervarietal. But the latter are generally due to a few genes with relatively large effects, and rarely to differences involving whole chromosomes or large parts of them. The reverse is true of differences between species. The number of genes involved is often great, and cytologically observable differences common. It is largely these latter which are the causes of interspecific sterility."

After this comes a discussion, occupying two chapters, of the effects of selection. The first part describes cases of stable populations, which have maintained the same numerical proportion between individuals of different types for long periods of time, and changing populations in which one type, owing apparently to environmental change and consequent selection, has increased rapidly at the expense of another. Then, natural selection having been shown to be an observable reality, and the different kinds of inheritable variations having been defined, there follows an inquiry into the extent to which the observable facts of evolution can be accounted for by supposing the one to be acting on the other.

Much of this discussion is based upon the recently developed mathematical theory of natural selection, a theory to which Prof. Haldane has made important contributions, and which he outlines in an appendix of forty-five closely printed pages. This is a most useful addition to the book, for many of the original papers are rather inaccessibly published.

Although Prof. Haldane inquires chiefly into the effectiveness or otherwise of natural selection as a cause of evolution, he comments briefly on other suggested causes, and makes damaging attacks from time to time against the Lamarckian position. The conclusion is that

> "it would seem that natural selection is the main cause of evolutionary change in species as a whole. . . . Although we have found reason to differ from Darwin on many points, it appears that he was commonly right when he thought for himself, but often wrong when he took the prevailing views of his time—on heredity, for example—for granted."

Finally, less scientific perhaps than the rest but excellent reading, there comes a chapter on the æsthetic aspects of evolution, in which the author, who has already told us why he believes in evolution, goes on to confess why he is glad that he believes as he does.

When Prof. Haldane concerns himself with present-day phenomena he is vividly interesting, but the reviewer was aware of a faint feeling of dissatisfaction when he came to the passages which extrapolate from present-day experience into the past. The trouble—which is due to a fault, not of the author but of the material at his disposal—arises from the following considerations.

Prof. Haldane deals of course in his discussion with the objection, which has so often been raised against Darwinism, that although natural selection accounts for the acquisition by an evolving race of advantageous characters, it cannot account for characters which are damaging, or which are simply indifferent. Palæontology gives examples of the evolution of characters which appear to be a hindrance rather than an advantage to their possessors, and systematists distinguish many species by differences of colour and shape which have no discernible survival value. To meet this criticism, Prof. Haldane points out, as Darwin did, but with a wealth of new examples, that characters which seem different are often linked together in inheritance and transmitted as a single unit. Thus various anatomically distinct strains of wheat differ also in their susceptibility to rust; the white and coloured populations of America die from different diseases; and there is evidence that immunity to measles is correlated with hair and eye colour. One can therefore account for the evolution of useless characters by supposing them to be accompanied by unknown advantages. Even a disadvantageous character might prevail if it was linked to a sufficiently profitable adaptation.

It will at once be seen that natural selection is a very formidable explainer of data. Indeed, short of abrupt discontinuity in the fossil record, it is difficult to imagine any facts that, properly manipulated, it would fail to explain. Imagine a fossil population consisting of individuals of two types—one, so far as we can judge from its structure, better adapted to the conditions than the other. If the well-adapted one is seen in the rocks to triumph and replace the other, well and good; if not, then one has only to postulate unknown characters linked to the visible ones to explain the issue. If *Eohippus*, instead of begetting and being replaced by the mechanically more efficient modern horse, had evolved out of it, the selectionist would only have to assume that the more toes a horse had the more immune it was against diseases.

The reviewer (who confesses that for the moment he has stopped reviewing) does not wish to suggest that the argument of linked characters is false. But it seems to him that by its aid the hypothesis that evolution occurred by natural selection acquires a facility that is almost indecent. Just as coffee can be too sweet, so a theory can explain too much—the first is undrinkable, the second is useless for scientific prediction. To be satisfyingly true, a theory should from time to time run the risk of disproof.

If we had a fossil record of Utopian completeness, how very different the state of affairs would be! Given a large collection of specimens of an evolving species all from the same level, one might perhaps determine from their sizes which individuals lived longest, and which died young. That would afford a basis from which the subsequent evolutionary history of the race could be predicted. But until that kind of check can be applied to it, the hypothesis that natural selection has been the main cause of evolution in the past is of a rather low order of truth. When it is applied to the horns of titanotheres or to the coilings and uncoilings of ammonites it is little more than specious. Our chief excuse for adopting it is that nobody can think of a better hypothesis—and that, after all, is a pretty poor one. Reinforced by the argument of linked characters, it can explain all the facts of evolution, but, skilfully handled, it could probably explain their converse equally well; and for that very reason it cannot at present be confirmed.

On the other hand, there is plenty of evidence in Prof. Haldane's pages that at least we are approaching a critical estimate of the importance of selection in such evolutions as occur to-day. There are the rapid advances in genetics and cytology and in the mathematical theory of selection; and there are the fascinating cases—all too few at the moment—in which a change in the composition of a population has been watched, one variety supplanting another. Here are opportunities for experiment and critical analysis, and promises of truths solid enough to satisfy even the most carping. The chapters in which the author gives an account of the present condition of this rapidly progressing branch of knowledge constitute by far the most exciting and valuable part of his book. G. P. W.

Universities Yearbook

The Yearbook of the Universities of the Empire, 1933. Edited by Sir H. Frank Heath. Published for the Universities Bureau of the British Empire. Pp. xxxi+975. (London: G. Bell and Sons, Ltd., 1933.) 15*s*. net.

IN issuing this admirable conspectus of British universities, the Universities Bureau, now in its twenty-first year, renders an important public service. The yearbook displays in convenient form authentic information regarding the personnel, organisation, regulations and recent activities of universities and thus obviates much laborious search among official calendars, many of which are to be found in but few public libraries. Facilitating, as it does, intercourse between seats of learning in all parts of the Empire, the yearbook becomes, as this intercourse develops, ever more indispensable. In addition to particulars given separately for each university there are generalised accounts of the universities of Great Britain and Ireland, of Canada, of Australia, of South Africa and of India, and these are from time to time rewritten: in the present issue the South Africa and India chapters have been revised and brought up to date, as those of Canada and Australia were in the two preceding issues.

In appendices covering two hundred pages are summaries of the conditions governing admission to various professions and careers for which university studies are a fitting preparation, the qualifications for admission to a first degree in the universities of Great Britain and Ireland, lists of open post-graduate scholarships, fellowships and grants for research available (whether within or without the Empire) to British nationals and lists of centres of scientific research and of scientific information (whether connected with the universities or not) with particulars of the conditions of admission of independent research workers.

In the present issue the presentation of the conditions of admission to the universities of Great Britain and Ireland and qualification for their first degrees has been further clarified—an improvement which will substantially enhance the value of the book in the estimation of the general public, as will also the further improvements that have been made in the general index. The memorandum and new articles of association of the Universities Bureau are published for the first time in the present issue together with the names of the representatives of the member universities. All the universities of Great Britain and Ireland are members, but of the remaining fifty-one universities in other parts of the Empire twenty are, it appears, not at present members of the Bureau.

Short Reviews

The Subject Index to Periodicals, 1931. Issued by the Library Association. Pp. x + 267. (London: The Library Association, 1932.) 70*s*.

THE Library Association is to be congratulated on having accelerated the rate of publication of the annual volume of its "Index to Periodicals", so that the volume for 1931 appears only eight months after that for 1930. For this promptitude we have to thank the editor, Mr. T. Rowland Powel, and the increasing number of voluntary contributors who help him in the work.

The present volume contains the titles of 25,650 articles selected from 582 periodicals. The periodicals examined are chiefly English and American. No less than 540 of these have been indexed. In addition, 23 French, Belgian and Swiss, 17 German and Dutch and two Italian periodicals have been examined.

It should be noted that, with few exceptions, no attempt has been made to index periodicals covered by the following publications: *Agricultural Index, Engineering Abstracts, Engineering Index, Index Medicus, Journal of the Society of Dyers and Colourists, Photographic Abstracts, Revue de Geologie*, Royal Meteorological Society's *Bibliography, Science Abstracts* and the Textile Institute's *Journal*. The subjects indexed are not confined to pure and applied science, for while poetry and fiction are excluded, the range of subjects dealt with is very wide. It includes, among other topics, art, architecture, music, language, literature, biography, education, law, medicine, labour questions, philosophy, peace and war.

The Changing Culture of an Indian Tribe. By Margaret Mead. (Columbia University Contributions to Anthropology, 15.) Pp. xiv + 313. (New York: Columbia University Press; London: Oxford University Press, 1932.) 28*s*. net.

DR. MARGARET MEAD's study of present conditions in an Indian tribe living on a reservation, of which the anonymity is preserved under the title of "Antler", deals more particularly with the position of the women. It is, in a sense, an experimental study in that it has been undertaken with a view of elaborating and testing methods of observation which, it is pointed out, will in the near future have to be employed in an increasing degree in ethnographical observation, owing to the rapid changes which are taking place all over the world among backward peoples, as they come more and more closely into contact with civilisation, and their customs and native economy are modified thereby. In a preface, Dr. Clark Wissler points out, for example, that the Indians whom Dr. Mead has had under observation, are living under two incompatible ideals. On one hand they are trying to preserve their old tribal ideals of community, and on the other hand they are forced to conduct their life in accordance with the white concept of competition. Dr. Mead's book, which has some valuable detail bearing on moral conditions among a partially detribalised people and on the modification of conditions in marriage, is thus of both special and general interest to the student of ethnology.

Pedigree Schedules: the Study and Preparation of Family Records. 11 pp. of Explanatory Notes, +30 Case Sheets and specimen Charts. (London: The Eugenics Society, 1932.) 10*s.*

THIS publication consists of a stout adjustable cover to which is attached a pamphlet of 11 pages of explanatory notes, a folded sheet of strong graph paper, destined to receive the pedigree chart, six blank leaves for comments on the pedigree, and thirty individual case sheets.

The explanatory notes are, up to p. 10, devoted to instructions for filling up the pedigree in standardised symbols and arrangements of generations. The greater difficulties of the individual case sheets are more lightly touched. Indeed the information asked for on these sheets is so slight as to be of little interest to the hypothetical descendants. Nationality and race are asked for, and the explanatory notes show that the latter question may be answered in such terms as ½ Slav, ½ Chinese. Spaces are left for the dates of birth and death, but marriage, perhaps on a modernist assumption that such a state is transient, fruitless, and of no interest to posterity, is not mentioned.

To be widely useful far more space should have been given to the occupational record and personal history of the subject, and space should not have been given for inquiries so vague as 'physical type'.

Land and Labour in China. By R. H. Tawney. Pp. 207. (London: George Allen and Unwin, Ltd., 1932.) 7*s.* 6*d.* net.

PROF. TAWNEY has written an excellent review of social, economic and educational conditions in modern China, taking the land and labour on the land as his starting point and the central core of the problem of future development. His book in part is based on his own observation and in part is an analysis of recent literature, of which a considerable proportion is by Chinese authorities. The special feature and chief source of interest in Prof. Tawney's work is its grasp of the Chinese attitude of mind towards Western civilisation and the recognition that in the final solution of the conflict of West and East now proceeding, in all probability it will be anything but a mechanical adoption of the machinery of progress, which in the long run will satisfy the Chinese temperament. As Prof. Tawney indicates, where we think in years or generations, the Chinese think in hundreds and thousands of years. Hence their tolerance of conditions which another people would feel to be unendurable, but also their faith in an ultimate solution.

The Frazer Lectures, 1922–1932. By divers Hands. Edited by Warren R. Dawson. Pp. xv+304. (London: Macmillan and Co., Ltd., 1932.) 15*s.* net.

THE Frazer Lectures, founded in honour of Sir James Frazer and to commemorate the completion of the third edition of "The Golden Bough", have now been delivered for ten years in succession in the Universities of Oxford, Cambridge, Glasgow and Liverpool in rotation. Among the lecturers have been the late Sidney Hartland, the late Canon J. Roscoe, Dr. A. Moret, Dr. A. C. Haddon, Dr. Marett, Prof. Westermarck, Prof. Malinowski, Sir Arthur Evans and Sir Arthur Keith. Although some of the lectures have already appeared in print, the convenience of having them together within the covers of this handsome and well-printed volume will appeal to all classes of reader, while marking the manner in which those representing different schools of thought have united to do Sir James Frazer honour.

The Races of Man: Differentiation and Dispersal of Man. By Prof. Robert Bennett Bean. (Highlights of Modern Knowledge.) Pp. vi+134. (New York: The University Society, Inc., 1932.) n.p.

DR. BEAN'S "The Races of Man" is a volume in a series published by an organisation in New York which exists for the popularisation of knowledge in science and art and now has offices in most of the more important countries of Spanish America. Dr. Bean's book is well produced and well and fully illustrated; but its text shows signs of over hasty preparation leading at times to statements perilously near misstatements. On such matters as racial differentiation and racial dispersal it is good and attacks its problems on broad lines; but in dealing with the origin and descent of man, the author does not appear to be abreast of either recent discovery or theory. Misprints are frequent.

Be your own Weather Prophet: a Book for the Holidays and After. By E. S. Player. Pp. vii+128. (London, New York, Toronto and Melbourne: Cassell and Co., Ltd., 1932.) 3*s.* 6*d.* net.

EVEN in these days of broadcasts, weather information is still profitable to the holiday maker, and this brightly written little book is full of weather wisdom. It sets out simply the relations of wind and weather to moving systems of isobars, and tells the reader how to diagnose the weather situation from his own observations, his only instruments being an aneroid barometer and a thermometer. The account of cloud prognostics is good, and the local peculiarities of weather are adequately discussed.

Climate and Acclimatization: some Notes and Observations. By Sir Aldo Castellani. Pp. viii+152. (London: John Bale, Sons and Danielsson, Ltd., 1931.) 7*s.* 6*d.* net.

SIR ALDO CASTELLANI describes with a wealth of technical detail the medical effects of tropical climates, especially of great heat and moisture and strong insolation. On the latter subject there is much to interest meteorologists, but in matters of meteorological theory the book is less satisfactory. There is an excellent bibliography.

Nature of Cosmic Rays*

By Prof. ARTHUR H. COMPTON, Ryerson Physical Laboratory, University of Chicago.

THERE are three kinds of experiments which seem to afford direct evidence regarding the nature of cosmic rays. These are: (1) the Bothe-Kolhörster double counter experiment, which compares the absorption of the particles traversing the counters with the absorption of cosmic rays; (2) measurements of the relative intensity of cosmic rays over different parts of the earth, designed to show any effect due to the earth's magnetic field; and (3) studies of the variation of cosmic ray intensity with altitude, which should follow different laws according as the rays are electrons or photons.

(1) The Bothe-Kolhörster experiment serves to measure the absorption in a block of gold or lead of the high-speed electrified particles that produce coincident impulses in two neighbouring counting chambers. It is found that this absorption is surprisingly small, about the same, in fact, as that of the cosmic rays themselves.

The simplest interpretation of this similarity in absorption is to suppose that the high-speed particles in question are the cosmic rays. There is, however, the alternative possibility that the primary cosmic rays are photons which eject high-speed electrons as recoil electrons when the photons are stopped, and that these recoil electrons are absorbed at about the same rate as the primary rays themselves. Theoretical calculations indicate that the recoil electrons should be absorbed five or ten times as rapidly as the photons which give rise to them. These calculations are somewhat uncertain because of extrapolation far beyond the wave-length region where the existing formulæ have been tested. For this reason, the equal absorption coefficients of the cosmic rays and the high-speed particles does not necessarily rule out the possibility that the particles in question may be recoil electrons excited by the cosmic rays. It would, nevertheless, be surprising if the formulæ were in error by so large a factor as five or ten, as would be implied if the coincidences are due to secondary electrons.

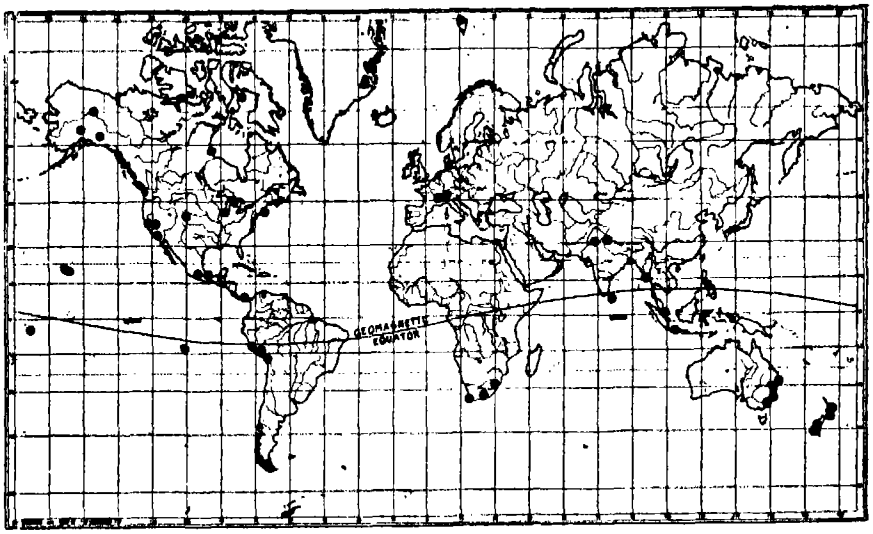

FIG. 1. Map showing major stations at which associated expeditions have made cosmic ray measurements during 1932.

(2) If the cosmic rays consist of electrified particles coming into the earth's atmosphere from remote space, the earth's magnetic field should affect their geographical distribution. This effect has been investigated theoretically by Størmer, Epstein, and recently much more completely by Lemaître and Vallarta. It appears that for energies less than 10^9 electron volts, electrons approaching the earth can reach it only at latitudes north of about 60°. For energies greater than about 5×10^{10} volts the geographical distribution is not affected by the earth's magnetic field. For intermediate energies, there will be a difference in intensity with latitude according to the distribution of energy of the incoming electrons.

Experimental studies of the relative intensity of cosmic rays in different parts of the world have been made by J. Clay, who made several trips between Java and Holland, and found consistently a lower intensity near the equator; Millikan and Cameron, who found but slightly lower intensity in the lakes of Bolivia than in the mountain lakes of California, and no difference between Pasadena and Churchill close to the north magnetic pole; Bothe and Kolhörster, who carried a counting tube from Hamburg (53° N.) to Spitsbergen (81° N.) and back, and detected no variations in the cosmic rays larger than their rather large experimental error; Kennedy, who, under Grant's direction, carried similar apparatus from Adelaide, Australia, to Antarctica, and likewise found no measurable change; and Corlin, who on going from 50° N. to 70° N. in Scandinavia found some evidence of a maximum at about 55° N. The prevailing opinion regarding the significance of these measurements has thus been expressed by Hoffman in a recent summary: "The results so far have on the whole been negative. Most of the observers conclude that within the errors of experiment the intensity is constant and equal, and those authors who do find differences give their results with certain reservations."

---

* Substance of an address presented at a symposium on cosmic rays, held by the American Physical Society at Atlantic City on December 30, 1932.

During the past eighteen months, Prof. Bennett of the Massachusetts Institute of Technology, Prof. Stearns of the University of Denver, and I have organised a group of ten expeditions, with some sixty physicists, and we have attempted to make as extensive a study of the geographical distribution of cosmic rays as could be done in a limited period of time. Fig. 1 shows the position of the eighty-one stations in different parts of the world at which measurements have been made. These stations are about equally divided between the northern and southern hemispheres. They have extended from latitude 46° S. to latitude 78° N., and from sea level to about 20,000 ft. (Figs. 2 and 3). When these data are brought together, they show a marked difference in intensity between the cosmic rays at temperate and polar latitudes, as compared with the tropical latitudes. At sea level the difference in intensity is about 14 per cent, at 2,000 metres about 22 per cent, and at 4,400 metres about 33 per cent. The change between the intensity for tropical as compared with that for temperate latitudes occurs rather sharply between geomagnetic latitudes 25° and 40°.

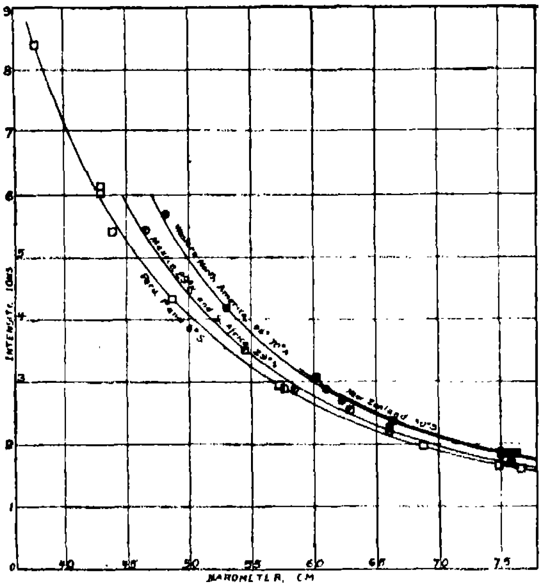

FIG. 2. Typical intensity-barometer curves, showing variation of intensity with altitude in different parts of the world. Circles, northern hemisphere; squares, southern hemisphere.

Comparison of the experimental data with the theory of Lemaître and Vallarta shows that the distribution of cosmic rays is about that to be expected if the rays consist of electrons entering the earth's atmosphere in two energy groups. One of these is of such great energy that it is not appreciably affected by the action of the earth's field. This group comprises in the temperate zone 88 per cent of the total radiation at sea level, and might, so far as these experiments are concerned, be classified as photons. At 4,400 metres this component constitutes 75 per cent of the total radiation. The second component is less penetrating and represents particles with an energy, if they are electrons, of about 7 × 10^9 electron volts. It is these particles which reach the earth at temperate latitudes but fail to reach it near the equator.

It may be remarked that even these less-penetrating cosmic rays have energies which are much larger than those that could be accounted for as recoil electrons resulting from photons, if these photons were to constitute the main body of the cosmic rays. According to Millikan, measurements of the absorption of the cosmic rays at sea level indicate that their energy, if they are photons, is of the order of 2 × 10^8 electron volts. This is so much less (a factor of 35) than that of the electrons responsible for the difference in intensity between temperate and tropical zones, that we would seem to be safe in concluding that the particles reaching the earth are not of the recoil type. On the other hand, the energy of 7 × 10^9

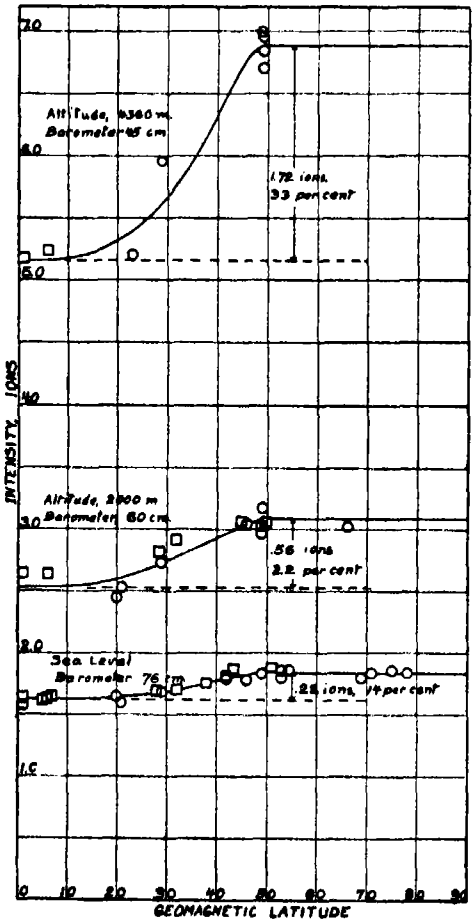

FIG. 3. Variation of cosmic ray intensity with geomagnetic latitude, as found for three different altitudes. The variation is more prominent at high altitudes. Curves calculated from Lemaitre-Vallarta theory.

electron volts demanded by the Lemaître-Vallarta theory for these particles would mean a range taken along the particle's trajectory of about three times the thickness of the earth's atmosphere. This is in accord with the fact that these rays penetrate the earth's atmosphere, but with difficulty.

This geographical study of the cosmic rays thus indicates that the less penetrating part of the cosmic rays, at least, consists of high-speed electrified particles. Regarding the more penetrating component, we conclude that if they are electrified particles, they must have an energy of 3×10^{10} electron volts or more.

(3) During the past two years, extensive experiments have been carried out studying the variation in the intensity of cosmic rays with altitude. The highest altitudes have been those reached by Regener with his sounding balloon and Piccard with his famous stratosphere balloon. We have also paid especial attention to this problem in our mountain experiments. In Fig. 4 the data from mountain and balloon observations are compared. These data show a rapid increase in intensity with altitude, continuing nearly exponentially to an altitude of 15 km., and from there approaching a limiting value as the apparatus is carried close to the top of the atmosphere.

If we suppose that the cosmic rays enter the earth's atmosphere as photons, any secondary electrons that may have been associated with them in space will have been removed by the action of the earth's magnetic field. We should thus have a beam of pure photons entering the atmosphere. At the surface of the atmosphere these photons will produce very little ionisation, for the ionisation results directly from the secondary electrons that pass through the chamber. The secondary electrons, however, arise only at the absorption of the primary photons, and will not approach their normal intensity until the photons have traversed a thickness of air about equal to the range of the electrons. This means that at very high altitudes the ionisation due to a beam of photons entering the earth must be almost zero. The ionisation current should rather approach a maximum at a depth in the atmosphere at which the cosmic rays are somewhat less than half absorbed, and should then gradually diminish in intensity as sea level is approached. Our high mountain experiments confirm the recent balloon experiments as indicating that no such high altitude maximum exists. This would seem to rule out the possibility that the cosmic rays can be photons entering the earth's atmosphere from remote distances.

If we suppose, on the other hand, that the cosmic rays are electrons entering the atmosphere from above, we should expect very much the kind of intensity-altitude curve that the present experiments show. It is well known that the ionisation per unit path by high speed electrons remains almost constant over a wide range of energies. Thus, if a beam of such electrons enters the atmosphere, it will produce nearly uniform ionisation down to such depths that an appreciable number of the electrons are stopped by the air. If the initial electrons were all travelling downward, there would be a rather definite limit or range where there would be a rapid reduction in the ionisation by the cosmic rays. If, however, the initial electrons entered in all directions, some of them would be stopped even in the upper layers of the atmosphere. Thus, supposing that the cosmic rays consist of electrons entering the earth's atmosphere from outer space, the general characteristics of the intensity-altitude curve can be readily accounted for.

If Regener's measurements from his balloon flights during the past summer are reliable, it appears that there is no detectable decrease in ionisation as the top of the atmosphere is approached. This would mean, in accord with the above reasoning, that no appreciable portion of the cosmic rays enters the earth's atmosphere in the form of photons.

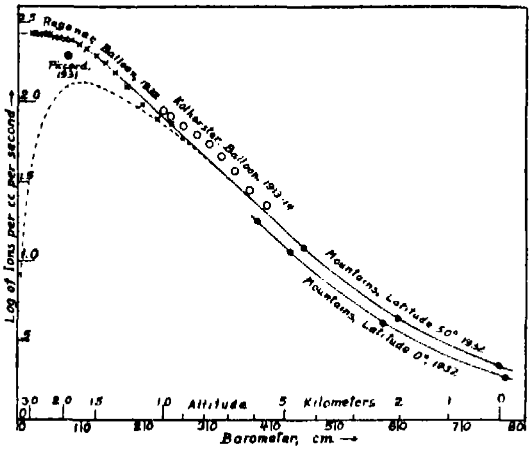

FIG. 4. Combined balloon and mountain data on intensity as function of altitude. Broken line, anticipated values for photons.

On the other hand, if the cosmic rays enter the atmosphere as electrons, they will produce photons just as cathode rays striking a target produce X-rays. Accordingly, at lower altitudes a mixture of electrons and photons will be present, and it may be expected that the photons will have the greater penetrating power. It is thus not impossible that the very penetrating cosmic rays observed by Millikan, Regener, and others at great depths under water may be such photons excited by the incoming electrons.

Although we have discussed the problem as if the electrified particles which seem to constitute the cosmic rays are electrons, it will be understood that the experiments that have been cited do not serve to distinguish between negatively and positively charged particles. The experiments are equally consistent with the view that the rays consist of protons or high speed α-particles. I find no way of reconciling the data, however, with the hypothesis that any considerable portion of the primary cosmic rays consist of photons.

The Old Ashmolean, Oxford

By T. E. JAMES

IN celebration of the occasion of the two hundred and fiftieth anniversary of the opening of the Old Ashmolean, Oxford, which falls on May 21, a series of events has been arranged. Addresses will be presented on May 22, by delegates of scientific and literary institutions, whilst a lecture is announced for the same day by Sir Arthur Smith Woodward on "Plot and Lhwyd and the Dawn of Geology". This will be delivered in the University Museum. Various exhibitions which are of cognate interest in connexion with the anniversary will be available to the public.

As an event of importance in the history of early science in Great Britain, but more particularly, perhaps, in relation to natural history, it is well and fitting to look back and recall the mode of origin of the Old Ashmolean. Time has changed much that was characteristic of this institution, leaving it now, one might almost say, no more than a dignified relic of the past. There is also something to record that is needful, respecting Elias Ashmole, the founder of the original *Musaeum Ashmoleanum.*

"Alumni Oxonienses" supplies a conveniently brief and helpful summary, where space is limited, of the main features of Ashmole's varied career. It runs :—"Born Lichfield 23 May, 1617. Educated Lichfield Grammar School. A chorister of Lichfield Cathedral; solicitor in Chancery, 1638; of Clement's Inn, 1640; an Attorney of the Court of Common Pleas, 1640; a Captain in Lord Ashley's regiment of foot at Worcester, 1646; barrister-at-law of the Middle Temple, 1660. Windsor Herald, 1660. Chief Controller of H.M. Excise in England and Wales, 1668. D.Med., by diploma (Oxon), 1669—." The anniversary of Ashmole's date of birth thus falls on the day after Sir A. Smith Woodward's promised lecture. Ashmole died on May 18, 1692, and he was interred in South Lambeth Church, where a black marble slab commemorates him in eulogistic terms. He had married three times, his third wife (1668) being the daughter of Sir William Dugdale.

Elias Ashmole, "skilled in chemistry, antiquities, heraldry, mathematics", and other abstruse studies, including alchemy and astrology, was among those persons, who, on May 20, 1663, were registered, and declared to be original fellows of the Royal Society, following upon the incorporating Charter of July 15, 1662. Ashmole's name, however, was included in that earlier and historic list of supporters of a proposed new society, whose declaration ran—"Wee whose names are underwritten doe consent and agree that wee will meete together weekely . . . to consult and debate, concerning the promoting of Experimentall Learning". This was dated, in the first instance, December 5, 1660, but names were appended after that particular date. On December 26, 1660, there is a minute that "Mr. Boyle, Mr. Henry Oldenburg, Mr. John Denham, Mr. Rawlins, Mr. Elias Ashmole, Mr. John Evelyn, and Nathaniel Henshaw, M.D., were proposed candidates for election". The association of Ashmole with these pioneer promoters of the new philosophy is of special though incidental interest. Ashmole not only signed the document quoted above, but also the Charter Book, when that fellowship roll was received and inscribed by original fellows as for 1663.

Hence, the Royal Society has two testifying signatures of Elias Ashmole. In election he preceded Edmund Waller and Abraham Cowley. On the other hand, Ashmole never served on the Council; nor did he appear to advance any schemes at hand. But he had divers interests and occupations as just excuse. Still, as regards activities in early science at Gresham College, or at Arundel House, Ashmole is a disappointing study.

In other directions, however, Ashmole's personal equipoise was assured. On June 18, 1660, he was introduced to the presence of King Charles II by no less a functionary than Thomas Chaffinch; and on the next day he was constituted Windsor Herald. When that folio on the History of the Most Noble Order of the Garter was published (1672), it was brought to the King by Ashmole.

We may now briefly consider Ashmole's connexion with the Old Ashmolean, and how it came to be established at Oxford, where scientific studies had already begun. On one of the rural sides of London, at South Lambeth, there had been established, by 1629, an extensive botanic garden, an adjunct to a residence, the latter a repository for 'rarities' in natural history. It was the home of John Tradescant, whom we hear of as married in 1607 at Meopham, in Kent. First as a gardener helping to stock the Hatfield demesne, next, he is travelling abroad and collecting assiduously, encouraged and stimulated by the Duke of Buckingham. It was the Duke's wish (so wrote Tradescant in 1625), that "I should deal with all merchants from all places". The South Lambeth house came, in time, to be known by the suggestive title of 'Tradescant's Ark'; its collections were noteworthy in the infancy of the study of natural history in England.

John Tradescant, son and heir, was imbued with his father's tastes and likings, and he carried on the collecting work at Lambeth when his father died in 1637. A decade or so later, we find that Ashmole was a frequent visitor across the Thames, and became very friendly with John Tradescant. In 1659 a diary entry by Ashmole records, "Mr. Tradescant and his wife told me they had been long considering upon whom to bestow their

Closet of Curiosities when they died, and at last had resolved to give it unto me".

After the death of John, the husband (1662), acute trouble arose in regard to the collections, settled, however, by Lord Chancellor Clarendon, in 1664, in favour of Ashmole, who was to "have and enjoy" the collection of rarities. Ashmole was then living in a house next to the Tradescants.

After Ashmole had obtained possession of the repository there came a period (about 1677), when it was urgently necessary to assign its contents. There were also certain manuscripts and books thought worthy. It was no use to cast eyes towards Gresham College. It was therefore not unreasonable, he thought, to offer his possessions to Oxford, his *alma mater*, but *conditionally* on the erection of a building to house them. He had been much honoured there in 1669 as a "curioso and virtuoso". Certainly a bold proposition, all things considered; nevertheless, it was gratefully accepted. Thereafter, the Ashmolean building took shape and became the designated habitation, erected at the charge of the University, fulfilling, at least in some measure, Ashmole's original hopes.[*] The foundation stone was laid on Thursday, May 15, 1679, and the Museum was opened on May 21, 1683. The Duke and Duchess of York, and their retinue, attended. There was feasting and jollity, and Ashmole (with whom was Mrs. Ashmole) was applauded and favoured to the top of his bent. Dr. Plot, the first custodian, gave a "sette speech". After the chief ceremony, the company went down to a newly fitted chemical "elaboratorie", where they witnessed some experiments, which are recorded as having given great satisfaction. A revival of the activities of the philosophers forming the Philosophical Society of Oxford, the original members of which had close contact with the Royal Society in London, occurring, their meetings were held in the Ashmolean for some time, and were both profitable and inspiring.

Space will not allow reference to the vicissitudes which later waited upon the Old Ashmolean, ending in neglect and disrepair. Dr. R. T. Gunther has dealt with these points, and of a brighter period, bringing in its train appreciation of new uses and recognition of the historic past.

---

[*] On January 26, 1678/9, a fire in the Middle Temple destroyed Ashmole's library, and many curios, in all probability, destined for Oxford.

Obituary

THE DUKE OF THE ABRUZZI

FEW men have led lives so full of interest and accomplishment as Prince Luigi of Savoy, Duke of the Abruzzi, who died on March 18 at the age of sixty years. Mariner, explorer, admiral, colonist, and man of science, he exhibited vision and initiative in every field of his numerous activities, and, by sheer tenacity of purpose, achieved success in the most arduous of ventures.

The Duke's connexion with the Italian navy commenced in 1879 when, at the age of six, he entered the service as cabin boy. From 1884 until 1889 he was occupied in study at the Royal Naval Academy. In those days Italy was not very well known in foreign countries and, to remedy this, the ships of the navy were sent on missionary work to distant lands and even round the whole world. Such patriotic propaganda found an enthusiastic supporter in the young Prince who, in the *Amerigo Vespucci*, the *Volturno*, and the *Cristoforo Colombo*, took part in several long voyages, ultimately attaining the rank of lieutenant. His first important naval command, in 1902, was that of the cruiser *Liguria*, in which he made a tour of the world lasting eighteen months. Further promotions followed, and the Duke commanded a squadron during the Italo-Turkish war of 1911–12, and was appointed to the supreme command of the Italian navy during the War.

As a traveller and explorer, the services of the Duke of the Abruzzi to science and to his country were outstanding. His early education in this direction was acquired during his teens in the Alps under the guidance of the well-known alpinist, Francesco Gonella. The Alps were also the scene of many of his later ascents and before he reached the age of thirty he had climbed, in some cases during the winter, all the most difficult Alpine peaks, some of which had not been previously conquered.

During his world-tour of 1894–96, the Duke saw the Himalayas for the first time and on his return to Italy he made preparations for an ascent of Nanga Parbat (8,115 metres). This expedition was, however, frustrated owing to an outbreak of plague and famine, which decimated the Punjab. The objective was therefore changed to a peak very different in character, Mount St. Elias in Alaska. Unlike Nanga Parbat, with a lower snow limit at about 5,000 metres, Mount St. Elias is covered from base to summit with glaciers, which debouch into the waters of the Pacific. The mountain—which is visible from the sea at a distance of 200 miles and has been known to navigators since the beginning of the eighteenth century—and its immediate surroundings were at that time completely unexplored. The expedition, consisting of the Duke and five companions, together with four Alpine guides, left Italy in May, 1897, and was joined at Yakutat Bay by ten American porters. Three days were occupied in crossing the wide plateau of the Malaspina glacier, and four laborious weeks in traversing the Seward, Agassiz, and Newton glaciers, fissured by enormous crevasses. Just over ten weeks after leaving Italy, the party camped beyond the Newton glacier at the foot of the great pyramidal mass of the mountain, and less than three days later reached the summit without casualty.

The observations made gave the altitude of

Mount St. Elias as 5,514 metres, in good agreement with the value (5,516 metres) calculated by Russell who, in 1891, reached a col situated at a height of 3,745 metres. Two unknown snowy peaks, observed in the west, were named Lucania and Bona, these being identified topographically and measured sixteen years later by American observers. A series of meteorological and glaciological observations was made, and collections of the minerals and minute fauna of the glaciers, and the first complete series of views of the St. Elias group were secured.

In the summer of 1898 the Duke visited Spitsbergen and in the following winter made an excursion by sleigh into Central Siberia. Preparations were then made—quietly, indeed almost secretly—for a north polar expedition. It was decided not to follow the plan adopted by Nansen in his earlier attempt, but to proceed by ship as far north as the currents allowed and then set out on foot. A Norwegian sealing vessel, re-christened the *Stella Polaris*, was acquired and the party of eleven Italians, with a Norwegian crew of nine, sailed in July 1899 from Archangel, where the sleigh-dogs had been shipped. Franz Josef Land was reached in three weeks' time and the ship proceeded through the archipelago to cast anchor off Prince Rudolph Island (lat. 82° 4′ N.), the most northerly island of the group. The ship narrowly escaped destruction in the ice, but was ultimately brought into a position of safety, and winter quarters were constructed on the island. During one of the trial sledge trips, the Duke was attacked by frost-bite, followed by gangrene, which necessitated the amputation of two fingers. It was not until about four months later that the weather allowed of the dispatch of the sleigh party. This was divided into three groups, to return at intervals. The first group of three, under Lieut. Querini, never came back, but Capt. Cagni's group, who were absent from the camp for 104 days, reached lat. 86° 34′ N., thus surpassing Nansen's record. In spite of the many difficulties encountered, the expedition was away only fourteen months, at that time the shortest period for a polar expedition.

Other expeditions organised by the Duke were those to Ruwenzori, in Central Africa, in 1906, when twelve peaks, all exceeding 4,600 metres, were ascended, measured and mapped; to the Karakoram Himalayas in 1909, when Bride Peak was climbed to a height of 7,500 metres (the highest altitude reached up to that time), the attempt to cover the remaining 150 metres having to be abandoned; and to the sources of the Webi Shebeli River, which flows through Ethiopia and Somaliland. On all these expeditions much valuable information of interest, not merely to geographers, but also to the whole scientific world, was collected and published. Their uniform success was due to the minute care taken in the preliminary preparations and, particularly, to the enthusiasm which the Duke showed and imparted to every one of his companions in every exploit he undertook.

The Italian Mission to the Abyssinian court in 1927 was led by the Duke, who later paid a second visit to the Webi Shebeli River and surveyed large areas in Abyssinia. Somaliland, where he had a large farm, claimed a good deal of his attention, and it was to his work on irrigation and on improvements in other directions that the opening up of this country was largely due.

Born in Madrid on January 29, 1873, shortly before the abdication from the Spanish throne of his father, Duke Amedeo of Aosta, brother to King Humbert of Italy, he passed away, after a life of ceaseless activity, in Somaliland, to the colonisation of which so much of his energy was devoted.

DR. JULIUS SCHMIDT

WE regret to learn from the *Chemiker-Zeitung* of the death of Dr. Julius Schmidt, extra-ordinary professor of organic chemistry at the Technische Hochschule in Stuttgart and director of the Chemistry Laboratory at the Höhere Maschinenbauschule in Esslingen, aged sixty-one years. A native of Baiersdorf in Bavaria, Schmidt studied under Knorr at the University of Jena and graduated in 1894. In 1900 he was appointed lecturer in organic chemistry at Stuttgart, where he carried out numerous investigations in the field of organic chemistry. His researches dealt particularly with nitroso-compounds, oximes and quinones, and with derivatives of phenanthrene and fluorene. He was also the author of numerous books and pamphlets on alkaloids, quinones, nitroso-compounds, organic magnesium compounds and pyrazoles. He also published a handbook of organic chemistry, which has been translated into English, and a yearbook of organic chemistry.

WE regret to announce the following deaths:—

Prof. Victor Goldschmidt, honorary professor of mineralogy in the University of Heidelberg, on May 8, aged eighty years.

Dr. William H. Holmes, formerly chief of the Bureau of American Ethnology and director of the National Gallery of Art, Washington, distinguished as a geologist, and a pioneer in field work in the archæology of North and Central America, on April 21, at the age of eighty-six years, at Royal Oak, Michigan, following on a paralytic stroke.

Dr. Leonard Huxley, editor of the *Cornhill Magazine*, author of "Life of Huxley", "Life of Sir Joseph Hooker", "Thomas Henry Huxley, a Character Sketch" and "Charles Darwin", on May 3, aged seventy-two years.

Mr. John Mackereth, a deputy conservator in the Indian Forest Service, on May 5, aged thirty-four years.

Prof. J. T. J. Morrison, emeritus professor of forensic medicine and toxicology in the University of Birmingham, on May 10, aged seventy-six years.

News and Views

Temperature below 0·27° K. reached in Holland

As we go to press, the following communication signed by Prof. W. J. de Haas and E. C. Wiersma of Leyden, and Prof. H. A. Kramers, of Utrecht, and dated May 15, has been received: "Debije has indicated a method of reaching very low temperatures by means of the adiabatic demagnetisation of paramagnetic salts. We have applied this method to CeF$_3$ with complete success. We determined a susceptibility curve in the region of temperatures usually reached with liquid helium, and by extrapolation from this curve in such a way that the result can only be too high, we found that the temperature reached in the adiabatic experiment was certainly below 0·27° K., even when the saturation was not taken into account. The other method of lowering the temperature, by reducing the vapour pressure of liquid helium, has resulted in a temperature of 0·82° K. reached by Kamerlingh Onnes, and later in one of 0·71, reached by Keesom."

Wool Industries Research Association

THE report of the Council of the Wool Industries Research Association, Torridon, Leeds, for 1932–33 refers to the satisfactory working of the voluntary levy scheme, the yield from which during the year has increased by 10 per cent. Subscriptions from the industry have reached the record figure of £11,087, or £514 in excess of the previous year. Together with a further reduction in expenditure due to certain internal economies and a new arrangement for the printing of publications and abstracts, this increase has enabled the Association to show a surplus for the year in spite of a reduction of £2,500 in the grant from the Department of Scientific and Industrial Research. Owing to economies effected by the Association in its work on raw wool during the last two years, the Empire Marketing Board has been able to extend the period of the grant for this work until September, 1933. The activities of the Wool Fibre Research Committee have been continued and representative samples of New Zealand wools have been selected as standards and submitted to New Zealand.

TRIALS carried out in Great Britain and in all parts of the Dominions of a sheep-marking fluid devised by the Association have proved the ability of the fluid to meet all the requirements of both the farmer and the manufacturer, in that it withstands climatic conditions satisfactorily and yet is completely removed from the wool by ordinary commercial scouring methods. Attempts have been made to render the present jute wool pad innocuous by impregnation, using a cellulose and a rubber latex dope. Both gave very promising results on trial in Australia and further experiments are being conducted on the same lines. Other experiments indicated that no real saving could be made on the weight of the fabric if the strength and durability were to remain unimpaired. Work on the standardisation of the methods of testing the fastness of dyed materials has continued under the supervision of a joint committee of the Association and the Society of Dyers and Colourists, and light standards consisting of seven red and seven blue colours on wool have now been finally selected.

Study Group on Managerial and Administrative Problems

INCREASING attention is now being devoted to the scientific treatment of the problems which arise in the management and administration of industry, and with the object of promoting discussion on these problems, a study group has been inaugurated under the leadership of Mr. W. R. Dunlop. Membership is being drawn mainly from among those who have attended Mr. Dunlop's course of training for management, though others who possess a degree in natural science or its equivalent and have taken a comprehensive course in management will be eligible to join. The latter qualification may be waived in special cases where a scientifically trained man has had managerial or administrative experience. The group is to be in the nature of an informal society and will meet regularly every three months, and in between as may be arranged, at 57 Gordon Square, London, or some other suitable place. The main feature of the meetings will be the scientific discussion of managerial and administrative problems and difficulties, especially in those industries in which science plays a predominant rôle. A monthly bulletin sheet will be distributed privately to members. This will contain items of managerial interest and references to new literature, while, for the benefit of country members, there will be included a summary of the proceedings at each meeting.

International Congress of Anthropological and Ethnological Sciences

IN accordance with a previous announcement, a conference was held at Basel on April 20–22 with the object of organising an international congress of the anthropological and ethnological sciences. Local arrangements were in the hands of Dr. F. Speiser of Basel and those who attended were received by Dr. F. Hauser, director of education, on behalf of the city of Basel and by Prof. Ernst Staehelin, Rector of the University of Basel, on behalf of the University. Twenty-three delegates, representing nine nationalities, were present and promises of support had been received from a large and representative number of anthropologists. Prof. J. L. Myres (Oxford) was elected president of the conference and Dr. Speiser and Mr. Houghton Brodrick (London), secretaries. Although some of the delegates expressed a strong preference for two separate congresses, to cover the anthropological and ethnological sciences respectively, it was decided that: (1) an international congress of anthropological and ethnological sciences be established; (2) the first congress be held, if possible, in 1934, and thereafter at intervals of four years; (3) on the invitation of the Royal Anthropological Institute, supported by the Joint

Committee for Anthropological Research and Teaching, the first congress be held in England, probably in London, in 1934. Draft statutes prepared by the president, the secretaries and Profs. Krause and Mauss, following closely the lines of the statutes of the International Congress for Prehistoric and Protohistoric Sciences, were considered and adopted. After nominations to the *comité d'honneur*, the permanent council and the offices of national secretaries, and votes of thanks to the City, the University and those who had been responsible for the work of the conference, the conference dissolved. A report of the meeting will be found in *Man* for May.

Radio Research in Great Britain

THE facilities for radio research carried out by the Department of Scientific and Industrial Research on the advice of the Radio Research Board have been improved by the unification of the Wireless Division of the National Physical Laboratory and the Department's Radio Research Station at Slough into a new Radio Department of the National Physical Laboratory. Mr. R. A. Watson Watt, hitherto superintendent of the Radio Research Station, is the superintendent of the new department. On the formation of the Radio Research Board in 1920 the National Physical Laboratory was entrusted with all work which required a laboratory equipped with instruments of the highest precision. Such work included the development of radio frequency standards, the study of problems of selectivity, aerial arrays and the generation of extremely short waves, as well as methods for the measurement of fundamental quantities necessary in accurate circuit design. Work requiring measurements in the field or on isolated sites was carried out at the Radio Research Station at Slough. The latter, which now ceases to be a separate research establishment of the Department of Scientific and Industrial Research, has, during its independent existence, earned an international reputation mainly in connexion with the researches carried out there on the travel of wireless waves, the electrical properties of the upper atmosphere, and the nature and origin of atmospherics.

A London Super Power Station

THE Battersea Power Station, which forms such a prominent landmark on the south side of the River Thames, will soon come into operation. It has been erected by the London Power Co., which was formed to secure the co-operation of the London electricity supply companies so as to reduce the cost by concentrating the generation of electricity in more efficient stations. It is one of the 'selected' stations adopted by the Central Electricity Board to supply the south-east of England electricity area. A description of it is given by I. V. Robinson in *World Power* for May. At present the station possesses two 70,000 kilowatt turbo-alternator sets and a 100,000 kw. set has been ordered. There are six Babcock and Wilcox boilers each evaporating 330,000 lb. of steam per hour at a pressure of 650 lb. per square inch and a temperature of 875° F. A jetty has been built parallel to the wharf which accommodates two of the company's 2,000-ton colliers at once. The coal is extracted by grabs and deposited on conveyors which take it to the boiler-house. Owing to the vicinity of the Houses of Parliament, Westminster Abbey, etc., it was necessary to take precautions so that the fumes would not act harmfully on these buildings. By means of induced draught fans the products of combustion are forced through 'scrubbers', passing across vertical surfaces in which water is flowing. They next pass over the main scrubbers consisting of cases of iron filings over which a stream of water flows. The iron acts as a catalyst converting SO_2 into SO_3. On reaching the chimney the gases first pass down a central chamber containing more steel sections and so have more oxide of sulphur abstracted. They then meet water containing alkaline salts which completes the purification. It is computed that 90–95 per cent of the oxide of sulphur has been eliminated.

The Cahn Hill-Improvement Scheme, Wales

LAST summer Sir Julien Cahn came forward with his generous response to the appeal made by the Welsh Plant Breeding Station of the University College of Wales for assistance towards the important work in progress relative to the improvement of hill land. The work had arrived at the stage when it was essential to conduct large-scale experiments involving not only the improvement of the grazing but also the control and management of the animals on somewhat novel lines. It was therefore necessary that the Station should obtain possession of suitable lands for the purpose, and that Prof. R. G. Stapledon should have associated with him a man fully competent in the management and breeding of stock. Mr. Moses Griffith, recently the agricultural organiser for Merionethshire and a well-known breeder of Welsh black cattle, has, therefore, been appointed to assist Prof. Stapledon as lands director to the scheme. A lease has been entered into with the Hafod Estate, for an area of approximately 2,700 acres of hill land. This comprises a mountain sheep walk of more than 2,000 acres together with a hill farm consisting of hill and cultivated land. The area chosen is on an estate with a long pioneering history behind it; for already at the end of the eighteenth century Johnes of Hafod was planting trees amongst these inhospitable hills and devoting himself with enthusiasm to improving the agricultural conditions of the district. Operations have been started and it is hoped that at least 50 acres of hill will be grassed out during the next two months. Each succeeding year large areas will be taken in hand by the methods which have been developed as the result of experiments conducted by Prof. Stapledon in various parts of Wales during recent years. In addition to the land at Hafod, possession has also been taken of about 70 acres of hill land near Knighton, in Radnorshire, and operations will be started there in the autumn.

Spike Disease in Sandal

SANDAL has long been a valuable forestry product in southern India and the mysterious disease termed 'spike' has been the subject of investigation during the past quarter of a century. Various bodies interested in sandal are collaborating, such as the Madras Forest Department, the Indian Institute of Science at Bangalore, the Forest Research Institute at Dehra Dun and others. A report on the progress made during the half-year ending September 30, 1932, entitled "Investigations on the Spike-Disease of Sandal" has been issued by the Institute of Science, Bangalore. The sporadic attacks of this pest have a strange parallel to those of foot and mouth disease in Great Britain. A recrudescence of the disease in an epidemic form has been noticed in the Beedamaruthupatti spike area. Pollarding, which has been carried out on a fairly large scale in the Galigattam and Manchi areas, has yielded significant data. So far, Manchi has the maximum percentage of disease-masking sandal plants. The entire freedom from infection of a few areas, Sanamavu and Thalli in North Salem and Chickabettakere in Coorg, has been established by pollarding. More detailed technical contributions will appear as scientific papers in the *Journal of the Indian Institute of Science*, *Dehra Dun Forest Research Publications*, and elsewhere. Meanwhile it is a valuable departure to issue progress reports so that the various investigators studying the pest, which causes so heavy a financial loss, should have early news of any results achieved.

Poison Control and its Effect upon Wild Life

IN California the control of the ground squirrel (*Citellus beecheyi*) by poison has given rise to strong protests in journals devoted to ornithology and bird protection, on account of the death by poisoning of numbers of wild creatures which are not injurious. We have already referred to some of these articles, and in fairness, it ought to be stated that the California Department of Agriculture, which is responsible for the organisation of the poisoning measures, accepts neither the "facts" nor the conclusions of the writers. In a summary of "The California Ground Squirrel Control Program", Eugene S. Kellogg states that those in charge of rodent operations were anxious to know what effect thallium, exposed on bait for ground squirrels, might have on other species of wild life, or how it might act as a secondary poison on predatory animals and birds. To check this point, the Biological Survey made a careful census of the wild life, then exposed baits far heavier than necessary for existing ground squirrel population in order to learn wild life tolerances. Careful checking by several observers during thirty days failed to show an appreciable effect on the beneficial animal life of the area. Hawks, quail and mourning doves, the species watched most carefully, appeared to be as numerous at the conclusion of the test as before (California Dept. Agr. Special Pub. No. 109). In this clash of opinion it is impossible for the outsider to discover exactly where the truth lies ; our impression is that there is a certain amount of bias on each side and an absence of the scientific detachment which would carry conviction. A basic fact which cannot be ignored is that ground squirrels are an economic pest which somehow must be controlled.

Smithsonian Field Expeditions in 1932

NONE of the many-sided activities of the Smithsonian Institute appeals so much to the imagination as the explorations and field work. During 1932, twenty-five expeditions were sent out or participated in for research in anthropology, biology, geology and astrophysics. These expeditions visited thirteen States of the United States, Europe, Canada, Alaska, Mexico, Hispanola, Jamaica, British Guiana and South-West Africa. Amongst the more interesting were a trip to various mining localities in Mexico for the collection of certain rare minerals and ores, a bird-collecting expedition to Hispanola, and a continuation of anthropological work in Alaska, where the characteristics of the living natives were studied, and the skeletal and archæological relics of an earlier civilisation were unearthed by excavation. The reduction in the Institute's income, both private and governmental, has occasioned strict economy in all lines and curtailment of some activities. Funds for publication have been cut nearly to one-half of the previous year's amount, with the result that valuable manuscripts have had to be refused or held up for a year, and the annual report, from which we have quoted above, has itself been cut to half its normal size. If the economies which must be enforced in other countries as well as in the United States, lead to the condensation of the published records of scientific work in some cases, and in other cases to more rigorous selection for publication, the experience will not be altogether wasted.

Agricultural History in Germany

THE Agricultural History Society of America, referred to in NATURE of March 19, 1932, p. 432, has a German counterpart in the Gesellschaft für Geschichte und Literatur der Landwirtschaft. Membership of this society is open to all persons interested, the subscription for persons resident outside Germany being 4 RM. per annum. The society's inquiries are not confined to central Europe. Investigation of the history of prominent agriculturists and of farms that have been in long-continued ownership by one family are noteworthy aspects of its activity. It publishes a small quarterly (free to members) containing articles, reviews and a list of current books and papers. Recent issues have included articles on the measures devoted to the development of Chinese agriculture under the Mongols, the Swiss Peasant Association, and the use of marl in ancient and medieval times. Information regarding the society can be obtained from Prof. W. Seedorf, Gosslerstrasse 16, Göttingen, Germany.

New Record for Deep Drilling

THE issue of the *Oil Weekly* of May 1 gives details of the establishment of a new depth record of 10,668 ft. for oil-well drilling, which has been achieved on the Kettleman Hills Field, California. This depth exceeds the previous record by 83 ft. The well has been drilled with standard rotary equipment and, so far, a 5⅝ in. hole is being made. It is destined to go to 11,000 ft. or even deeper if an oil-producing zone is not discovered at a shallower depth. One of the geological factors influencing the depth of this well is the great thickness of the recent deposits overlying very hard shale (Kreyenhagen). Operators believe in the possibility of very deep production at Kettleman Hills, and this is the first really serious attempt which has been made to test the lower formations in this region.

Asparagus Growing

THE imposition of a tariff on certain imported fruits and vegetables has made it possible for English growers to produce certain crops which before were unprofitable. One of these is asparagus, and it is therefore particularly opportune that the Ministry of Agriculture has issued a Bulletin (No. 60, "Asparagus", 1s. net) which deals with its cultivation and marketing. A useful preliminary account traces the history of asparagus from Roman times and also outlines the botany of the plant. Varieties are described in fair detail and experiments on the use of unisexual plants are outlined. Male plants tend to give a large number of buds whilst female plants produce fewer but larger sticks. Methods of cultivation in Italy, France, Germany, the United States and England are given, and marketing is also discussed. The main pest of asparagus, the asparagus beetle, is described, as are also several fungus diseases. The canning industry is growing in England, and its needs have been borne in mind by the writer of the bulletin.

Legal Medicine in the United States

THE resources of the various States of the Union for dealing with medico-legal problems in the administration of justice have been examined by a committee of the National Research Council, and the results of this survey are contained in a volume recently issued (Bull. Nat. Res. Council, No. 87, National Academy of Sciences, Washington, D.C., 1.50 dollars). It is pointed out that the determination of the cause of death, when a medico-legal question is involved, is the work of the skilled pathologist, who should be in a position to call to his aid the resources of bacteriologist, toxicologist, chemist, and others. Determination of mental responsibility is the work of the skilled psychiatrist. The detection of crime may at times require the application of pure and applied sciences in addition to the medical sciences. In the United States, there is as yet nothing comparable to the first-class medico-legal institutes of Europe.

Relativity

THE addresses and discussions at the conference on relativity in May 1930, which Prof. P. Langevin organised and presided over, have been published by Messrs. Hermann of Paris in the form of pamphlets of 14–30 pages at 6 or 7 francs in their series of Actualités Scientifiques et Industrielles. The principal titles are:—"Cinématique de la Relativité" by M. E. Bauer of the Collège de France, "L'Inertie de L'Énergie" by M. F. Perrin of the Faculté, "Méchanique Ondulatoire" by Prof. L. de Broglie of the Sorbonne, "La Théorie Einsteinienne de la Gravitation" by Prof. G. Darmois of the University of Nancy, "La Théorie Unitaire du Champ" by Prof. E. Cartan of the Sorbonne and "La Relativité" by Prof. P. Langevin. In all cases the subject is presented in a very readable form and Prof. Langevin's address summing up the general results is especially interesting. He also contributes a simple proof of the Lorentz transformation to the discussion on the kinematics of the subject.

Announcements

THE Bakerian lecture of the Royal Society will be delivered on Thursday, May 25, at 4.30 p.m. by Dr. J. Chadwick, who will take as his subject "The Neutron".

ON account of alterations and repairs which are being made to Flamsteed House, the official residence of the Astronomer Royal, it will not be possible this year to hold the customary garden party at the Royal Observatory on the occasion of the annual visitation by the Board of Visitors on Saturday, June 3.

THE annual congress of the South-Eastern Union of Scientific Societies will be held at Norwich on June 7–10. The president-elect is Prof. E. J. Salisbury, Quain professor of botany in University College, London. The presidential address is entitled "The Influence of Man on Vegetation". The congress will be divided as usual into the following sections: geology, botany, archæology, zoology, and regional survey. Several interesting excursions have been arranged in connexion with the congress. The local secretary is Dr. H. A. Castigan, principal of the Technical College, St. George Street, Norwich.

THE fourth International Congress of Radiology will be held in Zurich, under the presidency of Prof. H. R. Schinz, professor of radiology in the University of Zurich, on July 24–31, 1934. Members of radiological societies in all countries, and other persons introduced by such societies, are eligible for membership. At the general meetings the following subjects will be considered, among others: radiation genetics; mitogenetic radiation; structure analysis; identical physical measurement of the dose in X-ray and radium treatment; hard gamma-rays, cosmic radiation, earth radiation; and short-wave therapy. During the Congress, an exhibition of apparatus, photographic accessories, chemical products and scientific books will be on view. The general secretary of the Congress is Dr. H. E. Walther, Gloriastrasse 14, Zurich.

THE third International Congress of Linguistics will be held at Rome on September 19–26. The Congress will meet in three sections, of which the first will deal with general questions, the second with the Indo-European languages, and the third with the non-Indo-European languages. An organising committee has been formed, which is responsible for the arrangements for the meeting, of which the chairman is Prof. Matteo Bartoli and the secretary Prof. Bruno Migliorini. Subscriptions (members, 50 lire; associates accompanying members, 25 lire) should be addressed to the treasurer of the Congress, Prof. Vittore Pisani, Commizzione Nazionale italiana per la co-operazione intelletuale, via del Conservatorio, Rome (115). It is announced that the proceedings of the second Congress, held at Genova in 1931, are in the press and will be issued shortly.

DR. WITMER STONE, vice-president of the Academy of Natural Sciences of Philadelphia and curator of its Department of Vertebrate Zoology, has been elected an honorary member of the British Ornithologists' Union. Dr. Stone has been president of the American Ornithologists' Union and for twenty-one years he has edited the *Auk*, the official organ of the Union. Last year he was awarded the Otto Hermann medal of the Hungarian Ornithological Society (NATURE, 128, 670, Oct. 17, 1931). He has written a number of books on birds and other animals, and, with Cape May as a base for observations, has for many years carried on an intensive study of bird migration. Last year he completed, as editor, a revision of the "Check List of North American Birds", a monumental work in which is listed a description of every bird known to North America.

THE council of the Institution of Electrical Engineers has made the following awards for papers read during the session 1932–33, or accepted for publication: Institution premium to Mr. J. M. Kennedy and Miss D. M. Noakes; Ayrton premium to Mr. A. B. Read and Dr. J. W. T. Walsh; Fahie premium to Messrs. J. H. E. Baker and E. P. G. Wright; Kelvin premium to Mr. P. Dunsheath; Paris premium to Mr. W. S. Burge; Webber premium to Messrs. C. E. Horton and C. Crampton; Overseas premium to Mr. G. Yoganandam; Extra premiums to Messrs. J. C. Besly and H. V. Higgitt, Mr. Andrew R. Cooper, Mr. E. A. Hanney, Messrs. P. Hunter-Brown and C. J. Hews, Lieut.-Col. A. G. Lee, Lieut.-Col. F. A. Cortez Leigh, and Mr. R. P. Smith. The Wireless Section premiums have been awarded as follows: Duddell premium to Mr. E. C. S. Megaw; Extra premiums to Mr. L. B. Turner, Messrs. W. Ure, E. J. Grainger, and H. R. Cantelo. The following Meter and Instrument Section premiums have also been awarded: Silvanus Thompson premium to Mr. J. McG. Bruckshaw; extra premiums to Messrs. F. P. Burch and R. V. Whelpton, Messrs. C. Midworth and G. F. Tagg.

IN the leading article entitled "The Utilisation of Coal" discussing a symposium on this subject arranged by the British Science Guild, in NATURE of May 6, p. 633, disappointment was expressed that the authors of some of the contributions neglected to provide "the audience with complete comparative data from which the experts and laymen present could have drawn their own conclusions". Capt. Bernard Acworth informs us that the paper he was asked to read by the British Science Guild had as its title "The Economic Significance of Coal with Special Reference to Legislative Differentiation unfavourable to the Natural Expansion of the Coal and Coal Gas Industries". He deals fully, and accurately, with every aspect of the fuel economics of transport and power on land, sea, and in the air, in his recent book "Back to the Coal Standard".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant for abstracting work (chiefly engineering) at the Building Research Station, Garston (Department of Scientific and Industrial Research)—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (May 22). An assistant lecturer in engineering at the County Technical College, Wednesbury—The Director of Education, County Education Offices, Stafford (May 23). Two full-time teachers of engineering subjects at the Doncaster Technical College—The Secretary, Education Offices, Doncaster (May 23). A teacher in electrical engineering at the Technical Institute and Junior Technical School, Old Trafford, Manchester—The Principal (May 27). A head of the Department of Mechanical and Civil Engineering and a lecturer in geography at the Portsmouth Municipal College—The Registrar (May 27). A professor of mathematics at University College, Dundee (University of St. Andrews)—The Secretary and Registrar (May 31). A lecturer in biology at the Leicester College of Technology—The Registrar (May 31). An engineering assistant in the Engineering Department of the River Medway Catchment Board—The Engineer to the Board, 71A, Bank Street, Maidstone, Kent (May 31). An assistant lecturer in botany at the University of Birmingham—The Secretary, The University, Edmund Street, Birmingham (June 1). Visiting teachers in various branches of engineering, gas technology, mechanics and metallurgy at the School of Engineering and Navigation, High Street, Poplar, E.14—The Education Officer (T.1), County Hall, London, S.E.1 (June 7). A professor of dental surgery and director of the Dental Hospital at the University of Manchester—The Registrar (June 12). A reader (senior assistant) in pathology and a reader (senior assistant) in bacteriology in the Institute of Animal Pathology at the Royal Veterinary College—The Secretary, Royal Veterinary College, London, N.W.1 (June 30). A University lecturer in economics and politics at the University of Cambridge—Mr. E. A. G. Robinson, Sidney Sussex College, Cambridge. A woman lecturer in biology at the Lincoln Training College—The Principal. An organising secretary for the Association of Special Libraries and Information Bureaux—The Chairman of Council, ASLIB., 16 Russell Square, W.C.1. A technical assistant (Grade 3) for technical photography at the Royal Aircraft Establishment, Farnborough, Hants—The Chief Superintendent.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Beryllium and Helium

MANY years ago it was found that the mineral beryl often contains much more helium than can be accounted for by the traces of uranium and thorium which are present[1]. Recently returning to the subject, I have examined some thirty-five or forty beryls from different parts of the world and from different geological horizons. The richest of these contains 29·2 cubic mm. of helium per gram of beryl. The helium atoms number $2 \cdot 41 \times 10^{-4}$ of the beryllium atoms present.

If helium has accumulated in beryl as the result of atomic disintegration of beryllium, we should expect large helium content to be found only in the beryls of ancient formations. If on the other hand it has been trapped in some way when the mineral was formed, or if it is due to a short-lived radioactive product initially present in the mineral, we should expect to find large helium content in the younger beryls, since the opportunities for its escape have been less. The experimental results decidedly support the former alternative. Beryls from the younger rocks have not in any case been found to contain much helium. Beryls from the oldest formations usually contain a relatively large amount.

The probability that the main component of beryllium Be^9 is undergoing spontaneous disintegration is much increased by the recent measurements of Bainbridge with the mass-spectrograph[2]. He finds a value for the mass of Be^9 $9 \cdot 0155 \pm 0 \cdot 0006$, whereas the added masses of a hydrogen atom and two helium atoms amount to 9·01210. There is thus a considerable excess of energy available for spontaneous disintegration.

It was of interest to examine whether any α-ray activity was present adequate to account for the accumulated helium. The first experiments were made on the mineral itself, using the helium-rich specimen above mentioned. The walls of an electroscope casing were coated with it. The range of the α-particles was assumed to be 1 cm. in air, and the possible activity of the beryl was estimated from the ionisation at not more than $1 \cdot 47 \times 10^7$ α-particles per gram of mineral per annum. At this rate the helium observed would take more than $5 \cdot 43 \times 10^{10}$ years to accumulate.

Further experiments were made on a sheet of beryllium-aluminium foil (70 per cent Be) measuring 7·2 × 9·5 cm. which was kindly lent me by Mr. N. Feather, of the Cavendish Laboratory. The number of α-particles from this was estimated from the ionisation current at not more than $1 \cdot 55 \times 10^6$ per gram of beryllium per annum. At this rate the mineral would require more than $1 \cdot 05 \times 10^{11}$ years to grow the contained helium.

Either of these periods is much more than can be allowed; for the lead ratios of radioactive minerals never indicate an age of more than 2×10^9 years. Thus the helium in beryl cannot be brought into relation with any existing emission of α-particles. This conclusion, so far as it rests on experiments made with the mineral itself, does not depend on whether beryllium or some other constituent is thought to be the parent element.

It has recently been stated by Lange and Raitt[3] that beryllium has an α-ray activity of 1 cm. range and a 'half life' (half value period ?) of 10^{14} years. These authors consider that this is in striking accord with the presence of helium in beryls. But the ratio of helium atoms to beryllium atoms in the beryl above mentioned is $2 \cdot 41 \times 10^{-4}$, and this is the fraction of beryllium atoms transformed. If the half value period of beryllium were 10^{14} years, the time required would be $3 \cdot 5 \times 10^{10}$ years; about seventeen times as long as can be allowed.

While it appears certain that the small α-ray activity of beryllium found by Lange and Raitt will not account for the helium in beryl, the activity itself, if real, is of considerable independent interest. My own measurements with beryllium-aluminium foil led me to place the limit of possible activity three times lower, and I did not consider them as affording positive evidence of any activity. The calculation of emission from a thick layer is, however, not very satisfactory, and this may vitiate somewhat the comparison between the two sets of experiments. My own tests could have been pushed considerably further if enough of the foil had been available to line the electroscope casing completely. It is hoped to do this later.

RAYLEIGH.

Terling Place, Chelmsford.

A Theory of Fuel-Knock

IN an essay written three years ago[1] it was suggested that fuel-knock in an automobile engine might be associated with the presence of free hydrogen formed from the fuel used, and at that time the following facts were advanced in support.

(*a*) That in the combination of hydrogen and oxygen, variation of partial pressures, temperature and initial pressure produces rates of reaction of completely different orders of magnitude[2,3,4].

(*b*) That hydrogen in an engine cylinder gives rise to violent fuel-knock[6], while a fuel which does not contain hydrogen, for example, carbon monoxide, is not known to knock[5].

(*c*) That fuels comprising stable molecules, both liquid (for example, benzene[7]) and gaseous (for example, methane[8]) are not known to knock, whereas those comprising unstable molecules (for example, kerosene) knock readily.

The liberation of hydrogen from hydrocarbons and/or their primary oxidation products has been reported even during slow combustion[8,9,10,11], and conditions in an engine cylinder (where the advancing flame compresses unburned fuel ahead) are suitable for the breaking up of fuel molecules with a consequent liberation of hydrogen. If it be assumed that fuel-knock be caused by the rate of reaction between this free hydrogen and the available oxygen reaching a high order of magnitude (due to a favourable combination of partial pressures and/or temperature), certain effects should be noticed. In a knocking engine it should be possible to eliminate the knock by the addition of small quantities of hydrogen (thereby taking the partial pressure of the hydrogen out of the critical range); it should be impossible to detect an intermediate stage in the formation of water vapour from the hydrogen (for example, OH molecules); and the temperature of the water vapour molecules formed in the knocking combustion should be considerably higher than in normal combustion. Evidence of these three effects has been forthcoming.

(1) In unpublished work performed at the Bureau of Standards early in 1921 it was found that the use of hydrogen in comparatively small amounts eliminated fuel-knock and the high pressures resulting therefrom.

(2) In a direct spectrographic comparison of the flames from knocking and normal combustion in an engine cylinder, OH bands in the ultra-violet disappeared from the knocking zone only when fuel-knock was present; in normal combustion they were detected throughout the cylinder[12].

(3) In work now proceeding at the Bureau of Standards on infra-red radiation from an engine cylinder (preliminary accounts of which have already appeared[13,14]) there are indications that the spectral distribution of the radiation during knocking and normal operation is essentially the same from the region where no knock occurs, while radiation from water vapour molecules on wave-lengths between 5μ and 10μ shows an increase when knocking conditions are compared with non-knocking in the region where knock occurs. The only change from knocking to non-knocking operation was the necessary variation in the proportion of benzole mixed with a fuel of low anti-knock value to eliminate the knock.

More complete data, and a discussion of this theory in its relation to existing theories of fuel-knock and knock-suppression will appear later, though it may be mentioned here that the combustion of hydrogen has been found to be remarkably inhibited by the presence of small amounts of anti-knock materials[15].

My thanks are due to Prof. S. Lees, from whom I obtained the original idea that hydrogen might be responsible for fuel-knock, and the acting director of the U.S. Bureau of Standards, for permission to publish this note.

Hydrocarbon Combustion in an Engine

AN outline of a theory of the behaviour of 'antiknocks', and of the character of the knocking type of explosion, was put forward in a lecture at the Royal Institution in 1928 (see supplement to NATURE of July 7, 1928). The ideas discussed were obtained by inference from a variety of experiments, rather than by direct demonstration. It was not demonstrated with any certitude, for example, that peroxides were formed during a knocking type of explosion in an engine cylinder; neither was it proved that the metallic 'antiknocks' were in an oxidised state before being effective as 'antiknocks' in the engine.

These and other points in agreement with the ideas then put forward have now been demonstrated, and, as then suggested, are of importance in connexion with the process of combustion of certain hydrocarbon vapours. By sampling the gases at various moments during the cycle of an internal combustion engine, by means of a special device which can be operated over a very small crank angle, the amounts of aldehydes and peroxides, etc., have been determined. Substances behaving as peroxides rise to a maximum, and then fall off in quantity prior to the passage of flame past the valve, whereas the aldehydes are at a maximum 1/240 second later, when the flame reaches the valve. The amount of 'peroxide' appears to be connected with the phenomenon of knocking. Benzene gave rise to no measurable peroxides, though aldehydes were present in considerable quantity.

It has also been demonstrated that thallium, which acts as an even more powerful 'antiknock' than lead, when let into the engine cylinder as vapour by a special valve, is only effective when previously oxidised.

It is intended to publish an account of these experiments on the completion of the investigation.

A New Type of Photoelectric Effect in Cuprous Oxide in a Magnetic Field

WHEN a plate immersed in liquid air and placed in a magnetic field parallel to its plane is illuminated by a beam of white light perpendicular to its plane, an electromotive force E is produced between A and B (Fig. 1). This electromotive force changes its sign when the magnetic field is reversed, its absolute value remaining unaltered. We investigated the dependence of E upon the intensity of the magnetic field H and found that up to fields of about 2,500 gauss, E is a linear function of H, the maximum electromotive force at this field strength reaching 2·7 volts. It may be noticed also that when the plate is illuminated from the opposite side, with the direction of the current in the electromagnet remaining unchanged, the electromotive force is reversed in sign. The existence of this electromotive force must evidently be looked upon as an indication of

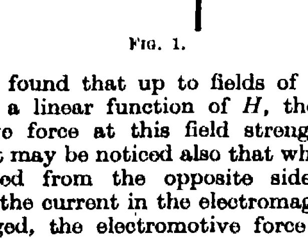

FIG. 1.

the fact that electric current is flowing perpendicularly to the plane of the plate. An examination of the sign of the electromotive force observed proves that the direction of the supposed flow of the negative electrons coincides with the direction of the light beam, assuming that under the influence of the magnetic field the electronic current is deflected in the normal way.

A characteristic feature of the effect may be noted, namely, that it disappears completely when a source of red light is used. The electromotive force is nearly independent of the intensity of light. We could not find the effect at room temperatures. The whole of the facts observed involve the assumption that the effect represents a peculiar Hall-effect of the moving photoelectrons produced at the entrance of the beam of light into the specimen. The proportionality between the electromotive force and the field strength gives strong evidence in favour of this supposition. This idea is supported, moreover, by the fact that the electromotive force is nearly independent of the light intensity. For example, the increase of the intensity of light augments the number of photoelectrons, which makes the Hall constant decrease (the Hall constant R is inversely proportional to the concentration of the conducting electrons). The observed electromotive force is a product of both effects. We are investigating the new effect further and we hope to publish shortly a complete account of this work.

Elastic Electron Scattering in Gases

THE investigations by Arnot[1] and others of the scattering of electrons in gases show that marked diffraction minima occur in the angular scattering curves. Their measurements show also indications of an anomalous course of the velocity scattering curves. Still, as only the relative values of the scattering are determined, a comparison of the scattering through a constant angle for different electron velocities is subjected to incontrollable errors.

A method described by the writer[2] makes it possible to determine the absolute values of the scattered intensity I_θ – the total scattering being $2\pi \int I_\theta.\sin\theta.d\theta$. The results for elastic collisions in helium[3] for velocities between 30 volts and 400 volts and at angles $\theta = 45°$ and $90°$ show velocity scattering curves, which gradually converge towards the classical nuclear scattering at high velocities.

Recent measurements at $\theta = 45°$, $90°$ and $135°$ in neon and argon, however, have revealed marked anomalies in the velocity scattering curves. In Fig. 1 the value of the scattered intensity I_θ is plotted against the velocity (expressed in volts) of the electrons in a doubly logarithmic diagram, and the scattering through 90° observed in helium, neon and argon is shown as heavy lines. In this representation, the classical nuclear scattering curve $I_\theta = e^4Z^2/m^2v^4\sin^4\theta/2$ appears as a straight line. In Fig. 1 the dotted lines give the classical scattering for different values of the nuclear charge (Ze). It will be seen that at high velocities the scattering in all the gases, helium, neon and argon, converges towards the scattering of their nuclei, corresponding to $Z = 2$, 10 and 18 respectively. In neon, however, the scattering passes through a marked minimum at 90 volts, while in argon a discontinuity in the curve is found at about 250 volts.

While for high velocities the scattering in argon may be described as a scattering due to the total nuclear charge 18, the scattering at smaller velocities converges towards an effective nuclear charge of about 6. In scattering experiments with $\theta = 135°$, where the discontinuity in the argon curve is more marked, the scattering at smaller velocities follows the nuclear scattering curve for $Z = 5$, before converging towards $Z = 18$ at higher velocities. In the argon atom the outermost group of electrons consists of 8 electrons, and colliding electrons penetrating into this group will therefore be under the influence of an effective nuclear charge smaller than 8. If the velocity of the electrons is large, the electrons may penetrate through the outer group and the total nuclear charge 18 will determine the scattering. It seems as if this rough picture is to some degree justified by the measurements.

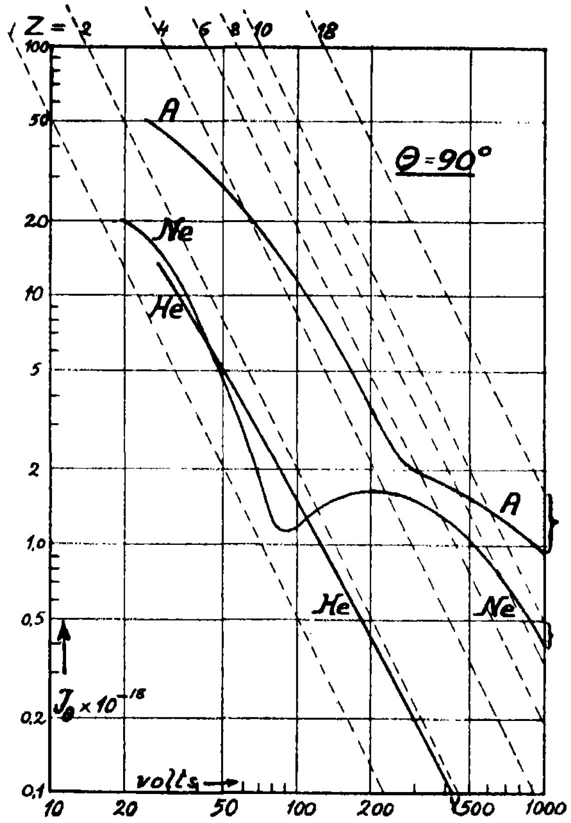

FIG. 1.

In neon the sharp minimum for velocities of about 90 volts allows of no such explanation and is probably due to some resonance effect of the same kind as that observed in the Ramsauer effect. The velocity (and potential) at which the minima or discontinuities are found changes with the scattering angle θ; as a rule they shift towards smaller values of the velocity when the angle θ increases. This may be connected with the fact that, according to the classical theory, the large angle scattering is due to electrons penetrating more deeply into the atom, and accordingly the total nuclear charge will govern the large angle scattering down to smaller velocities than the small angle scattering. At small angles, therefore, the scattering due to the total nuclear charge is first found at comparatively larger velocities. A closer explanation, however, of the anomalies observed will, of course, require a detailed quantum mechanical treatment.

Ideas of 'Time' and 'Events'

1. Is 'time' conclusively or adequately defined by the statement that the 'time' of an 'event' in systems in motion varies according to the position of the 'observer' of the 'event'? This implies (1) that 'time' is a characteristic or property of, and is inherent in, an 'event'; and (2) that both 'time' and 'event' are functions, so to say, of an 'observer'. Therefore, if no 'observer' function, an 'event' cannot occur and the property 'time' is eliminated. If, however, an 'event' be more scientifically defined as an electromagnetic relationship between two bodies or points in space, it will occur whether observed or not (for not all bodies are observers) and 'time' is again eliminated. The question may therefore be asked: Is 'time' a characteristic of Nature or merely an idea of the observer? (See 4 and 5 below.)

2. The statement above is also incomplete in that it does not indicate how the 'time' of an *observed* 'event' is related to other events in the experience of the same observer (whether or not he be in the same position relatively to the whole system), nor how it is related to those events he has not observed but which he knows have taken place. If 'time' consist of cross-calculations of *moving* 'events' as amongst a *number of observers*, how can I or my children determine which of us arrived 'first' in this world of change? A human being has memories of past, and expectations of future, experiences; but his consciousness of the three 'tenses of time' does not depend on that of other observers in space. The sense of the 'lapse of time', of 'before and after', is peculiarly human and individual. My sense of change and the passing of time is independent of the fact that day dawns earlier for observers to the east. I should remember the past and anticipate the future were there no inhabitants beyond my own neighbourhood.

3. Further: although we record 'periods of time' according to solar and lunar phenomena, we have no standard 'constant' by which to measure human conceptions of duration, of 'lapses of time'. These vary not only with individuals but also with the individual's mental state; and a man may even become oblivious of 'time' in reverie or day-dreaming and in states of intense mental concentration, of meditation on principles, *not* passing events, just as does an artist intent on some creative work. The idle day-dreamer and the active genius lose their consciousness of personal relationship with objective physical events and come back to awareness of 'time' with a start. The genius, however, usually has something to reveal to time-bound mortals from those regions of the mind that are 'beyond time' although he may have difficulty in expounding it for our comprehension. It is commonly known, too, that 'time is long' for those in pain or remorse but that there is no consciousness of the 'lapse of time' in states of deepest joy and happiness. Hell is the perpetuation of 'time', heaven *its obliteration*! *'Time' is thus something* created entirely by ourselves; it is not a predicate conception, not something *a priori*. It is an individual affair, present or absent according to the molecular conditions of the frequency-levels in which the mind functions.

4. Is 'time', then, indeterminate, independent of moving events, an illusion of man? If a genius can annul 'time' in respect to the 'object' of *his* inner sense he must be able to distinguish between the *real being* of physically sensible objects and *our knowledge* of such objects as ordinarily assumed, stated or formulated by science. It is now admitted that *this knowledge, while dependent on, is limited by, the instrumental means of observation.* (For example, *vide* NATURE, March 25, pp. 422-3.) That is, we form an idea of the nature of an 'object' from the characteristics of the perceptible phenomena evoked by its invisible interactions with the measuring instruments; and this conception cannot, of course, represent, or be actually 'like', the *object itself.* This is true, also, even of those 'objects' which are reflected directly by our senses. But we have no warrant to conclude that there is no 'object' apart from our idea, that no 'object' exists independently of our observation by whatever means; for *neither we nor our instruments could have caused the sensible experience or the observed phenomena without a something with which to interact.* To deny the reality of the object's being is tantamount to denying that of the observer's! Nevertheless, it is claimed that 'time' is a *sine qua non* of any existence whatever, and there can be no 'matter' other than the physical mechanical motion of 'waves' or 'particles' because 'time' is relative and simultaneity impossible; and, consequently, that, beyond the perceptible physical, *nothing* exists that could function as, or constitute, an unthinkable absolute 'event' or 'standard time'. Thus 'events' close round human genius and shut it in a time-world of illusion, bound and blinded by the means of observation he has himself created. A spider caught in his own web!

5. Science has no evidence, however, that 'time' is a property of Nature, although the cosmos is doubtless in one sense a gigantic chronometer. What we with our limited powers of observation term the *past* and the *future* with respect to the universe or any particular cosmos, is potentially objective *now.* The universe *simply is.* The totality of its parts, frequency-levels and latent worlds or solar systems are a self-contained present. Otherwise, the recurring precipitation and condensation of *fundamental* types —stellar and terrestrial—would be impossible, unless, indeed, science can indicate how objectivity or manifestation could arise absolutely *ex nihil.* Discussions on simultaneity are irrelevant chimeras, for if the properties of bodies were absolutely identical they would be in the same 'place', as surely needs scarcely be said; that is, there would be no differences of 'potential' and no differentiated objective world. In that condition of space there can be no 'position', no location, no extension and no 'relativity'; but, as our ordinary human consciousness depends on concrete objective contrasts and has no experience of possible abstract subjective distinctions, we are unable to imagine or to describe in terms of present-

day scientific conceptions a state of self-subsistent spatial activity consisting throughout of uniform, synchronous pulsations or vibrations. Our only alternative is to try to explain scientifically, *without this 'hypothesis'* ; (1) how the universe coheres as one whole ; (2) how the cohesion of individual bodies is maintained ; (3) how different 'potentials' originate ; and (4) 'where' or in what kind of rare state of electrical accumulation that which manifests periodically is held in latency—including the *genius* of man.

Light-Producing Powers of Sponges

IN his letter published in NATURE of February 18, p. 242, Dr. Crossland directs attention to the interesting fact that the most remarkable polychæte worm, *Syllis ramosa*, first discovered by the *Challenger* expedition at a depth of 140 fathoms, was found by him at a depth of only 1 fathom. Dr. Crossland describes how he obtained the worm from a siliceous sponge, stating that his method is the only way by which the bulk of the smaller fauna inhabiting coral reefs and sponges can be obtained. I have used another method with very satisfactory results.

Examining the list of light-producing animals, in which sponges are frequently mentioned, I observed at Villefranche sur Mer the surprising fact that different sponges living in the shallow waters were giving a very beautiful light. By accident I found one night a phosphorescent sponge of very fragile character ; breaking it and separating the two pieces very slowly from each other, I could see a number of very delicate shining threads stretching between the two pieces. I took some of these threads and brought them at once on a slide under the microscope. At the first glance I was able to identify the threads as branches belonging to a small phosphorescent annelid. Considering it probable that the animal, if short of water, would try to get again into its accustomed element, I poured the water out of the bowl, in which the 'light-producing' sponge was lying, and then attached the sponge to the edge of the inclined bowl in such a manner as to allow the water to drip slowly out of the sponge into the bowl. The next night I was amazed to see the abundance of small fauna assembled in the water, which had come out of the sponge, among it two little phosphorescent *Polycirrus aurantiacus* (Fig. 1), scarcely 5 mm. across, which were able to extend their branches to 40 mm. in all directions.

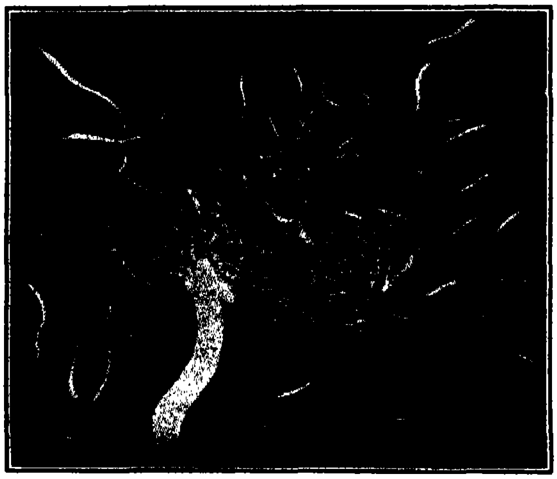

FIG. 1. *Polycirrus aurantiacus*.

I used the same method to get small animals out of different hiding places such as pieces of porous rock, etc., and could also fix particularly delicate animals, which often suffer under a narcotic, without damaging them.

The question whether the sponges are to be included among the light-producing animals has thus been decided.

The Dodo and the Aphanapteryx

THE paragraph in NATURE of April 29, p. 615, on the Edwards dodo painting reminds one that this famous picture has a double interest. If one examines it as it hangs in the Bird Gallery of the Natural History Museum, one notes that behind the dodo is figured a long-billed bird referable to no known species of stork or ibis. The unknown is straight-beaked and of a reddish hue varied with black, feebly recalling the plumage of a corncrake ; it holds a frog in its bill. The occiput is slightly crested and the legs sturdy as if for swift running.

Now all these characters except the bill occur in the poulet rouge or aphanapteryx as figured by Hoefnagel in his book of drawings of the imperial menagerie at Ebersdorf about 1610. Hoefnagel's bird had the bill curved instead of straight, but this may be due to sex or maturity ; the length in both specimens is apparently the same. It seems probable that in the Edwards painting one sees the second known specimen of this long extinct creature, and like the first one drawn from life by a competent artist. This bird, like the dodo, inhabited the Mascarene Islands and a figure of it—long unrecognised—appeared in Strickland and Melville's volume on "The Dodo and its Kindred".

Fusion of Pycniospores with Filamentous Hyphæ in the Pycnium of the White Pine Blister Rust

THE pycnia of the white pine blister rust are of the sub-corticular type as described by Arthur[1]. They may be characterised as extensive crust-like layers without definite delimitation and not having a well-defined ostiole and paraphyses such as are common to many of the leaf-inhabiting rusts. The pycnial crust consists of a dense layer of stromatic tissue formed by the anastomosing of the rust mycelium. From this layer arise the slender, erect, pycniosporophores, which are closely compacted in a palisade arrangement. Occasionally, a filamentous hypha is seen that projects for some distance beyond the common level reached by the sporophores and, although similar to them in structure, its diameter is usually greater and it is more irregular in outline. No cross walls have been observed in these hyphæ. A single nucleus is present, usually near the base. Often the tips of such hyphæ are bent over into a procumbent position due to the pressure of the overlying host cells. These hyphæ were first reported by Colley in 1918[2], who mentions their presence without comment.

For cytological study, fresh pycnia of the white pine blister rust were fertilised by interchanging the pycniospores, and, after a period of 48 hours, were fixed in Flemming's weaker solution together with an equal number of unfertilised pycnia of similar age. A copious exudate of nectar containing pycniospores was present on both sets of pycnia. Sections of both fertile and infertile pycnia were made as thin as 3 μ and stained with a modification of the triple stain. Both contained a few of the filamentous hyphæ described above, but in the fertile preparations eleven cases of pycniospores fusing with these hyphæ have been observed, while no case of fusion was found in the sterile preparations. These fusions are similar to the unions recently reported by Craigie[3] for the sunflower rust.

The pycniospores were united to the ends of the hyphæ by short tubes that were longer and of a somewhat smaller diameter than those illustrated by Craigie[3]. A few of the pycniospores seemed to be empty while others contained nuclei in the usual position. Actual migration of nuclei through the short connecting tubes has not been observed. Whether these tubes are extensions of the filamentous hyphæ or germ tubes sent out by the pycniospores remains to be established. A more detailed account covering the investigations undertaken on this subject will be presented at a later date.

Lignin Content of Cellulose Products

IN the working out of a new method of determination of cellulose, especially suitable for cereal straws, we have recently had occasion to determine the lignin contents of cellulose products obtained by various means. Chlorinations, either gaseous or in solution (as our new method involves) were continued until there was no trace of a characteristic red colour on the subsequent addition of sodium sulphite. In spite of this, however, the lignin contents of the products from a number of straws were, in general, between 2·5 and 3·0 per cent.

The lignin determination depends on the resistance of lignin, first to cold 72 per cent sulphuric acid, and later to boiling with more dilute acid. Pure cellulose under such conditions yields only a trace of apparent lignin, no doubt due to slight charring or caramelisation. Starch and glucose similarly yield only a trace of apparent lignin. A pentose sugar, on the other hand, gave with this treatment an appreciable quantity of some material as resistant as lignin and determined as such in the accepted methods.

Natural celluloses from woods and straws are known to consist of 'true' cellulose associated with other polysaccharide material, known as 'cellulosans'[1]. It seemed possible, therefore, that the lignin found in straw celluloses might be apparent rather than real, and be in truth derived secondarily by the action of the sulphuric acid, on the 'cellulosan' or pentosan fraction of the natural cellulose. Accordingly, by mild hydrolysis with 5 per cent acid for 1 hour, this fraction was largely removed. The apparent lignin content of the residues fell by 25–30 per cent in every case, indicating the correctness of this view. However, the residual lignin contents were even then much greater than the figures obtained on most wood celluloses, and, moreover, could not be reduced by gross over-chlorination and repeated sulphite extractions. We are, therefore, of the opinion that, while a part of the apparent lignin content of celluloses from cereal straws is secondarily produced from the cellulosan fraction, there is nevertheless a portion of true lignin (or some other acid-resistant material) very tenaciously retained by the cellulose itself and possibly in combination. We shall investigate this point further in an attempt to characterise or extract this small residual fraction.

In view of this observation that apparent lignin may be formed from the pentose grouping, we consider that the whole question of the determination of lignin by the 72 per cent sulphuric acid method must be critically re-examined. The results usually given for straws and hardwoods will probably be found to be too high. Those for softwoods, in view of the smaller content of pentose material, are probably much more nearly accurate. By submitting straws to an acid pre-treatment (5 per cent sulphuric acid for 1 hour) before the determination of lignin and removing thereby the major part of the pentose material present both as polyuronide hemicellulose and as cellulosan, the apparent lignin content was lowered by 25 per cent or more. It seems likely that this lower figure is the true value.

Whale Shark in the Waters Around Ceylon

WITH reference to Dr. Gudger's letter[1] on the above subject, I am inclined to agree with the view which his last paragraph implicates, namely, that *Rhineodon typus* is a rare visitant to the waters around Ceylon.

During a residence of nearly twenty-three years in Ceylon, I have neither seen a whale shark nor have I heard of one having been washed ashore. It seems scarcely likely that this shark, with its great size and peculiar characters, could have escaped the notice of the fishermen.

This negative evidence, however, is not altogether convincing. I am reminded of the occurrence of whales in South Indian waters. After considerable experience of marine biological surveying in the seas around Ceylon, I should have been prepared to say that although whales are occasionally seen they are relatively rare and could certainly not be fished profitably for commercial purposes; yet a whaling expert, who came to Ceylon two years ago with the intention of establishing a whaling station in Ceylon, assured me that whales were more common than I had supposed and that commercial whaling off the coast of Ceylon could be carried on successfully.

It is possible, therefore, that the giant shark *Rhineodon typus* may be more common in South Indian waters than the small number of reliable records would lead us to believe.

Research Items

Stone Age Culture in Uganda. A stone age culture discovered at Magosi in Uganda has been described by Mr. E. J. Wayland and its affinities discussed by Mr. Miles C. Burkitt (*J. Roy. Anthrop. Inst.*, **42**, pt. 2). The site of the discovery is a platform at the base of a granitic rock on the west side of a saddle in bold hills. Excavation revealed an ancient water-cistern of natural origin, mainly filled with brick earth and lined with an 18-inch layer of rock-rubble. In this latter and above it was a zone rich in microliths. Below the rubble was rock-sand representing the disintegrated sides of the cistern. The depth of the archæological deposits was found to be 11 ft. There was no definite stratification, and no great change in culture throughout the deposits; except that the implements of the bottom levels were rather more primitive, and the middle levels were the richest in well-made tools. Two groups occur side by side: (1) pygmy cores and tools; (2) discs and points, the latter tending towards the Still Bay type of South Africa. In South Africa the two groups, the pygmy (Wilton), a neanthropic group, and the Still Bay culture are not found in association and are of different age. It has been proved that the Still Bay culture is the result of a contact between an African Middle Stone Age people and a neanthropic people; and this appears also to be true of Kenya. The Magosi pygmies are much more like the true Wilton of Kenya and South Africa than the pre-Wilton pygmies of upper palæolithic and Elmenteitan levels of Gamble's Cave. Yet in both areas Wilton appears definitely later than Still Bay; while the archaic appearance of the Magosi industry suggests that it belongs to an older age than the true Wilton. This is borne out by its association with a Still Bay industry. A further suggestion follows. Uganda may be an area in which took place a fusion between a Middle Stone Age people, who had developed the Still Bay point, and a neanthropic race, the fusion producing a proto-Wilton industry which migrated south and developed into the true Wilton.

Prehistoric Gold-Mining in South India. A communication from Mr. L. Munn, of the Hyderabad Geological Survey, records personal observations of an ancient gold-mine in Hyderabad. In sending these notes, Mr. Munn expresses a fear that much information gained by engineers during the last fifty years, but unrecorded, may be lost unless action is taken, and hopes that his notes may elicit further information. Beyond a report by Maclarren in the *Records* of the Geological Survey and the book by that author, Mr. Munn is unacquainted with any information on the subject. His own experience was gained at Hoonkoni in the Deodrug Taluq of the Raichur District. Here the old workings are a series of pits, 615 ft. in length, which, judging from the debris, yielded a panning value of 5–8 dwt. to the ton. The reef was worked as an open-cut to a depth averaging 20 ft. by fire-setting and breaking with stone hammers. This is evident from the amount of wood-ash encountered and the curiously concave section of the portion of the reef remaining. After about 20 ft., a ridge of solid ground, about 5 ft. thick, was left. It is thought that this was intended to prevent rock from falling from above, as well as to avert flooding of the lower levels by the monsoon rain-waters. At intervals in this rib, shafts were opened, and when the shafts were sufficiently far through, lateral excavations were made. Evidently hammer-stones were freely used. Working by fire-setting in a narrow shaft, with the object of leaving the rib of solid earth, tended to produce the ever-increasing flattened oval. There is no evidence for the use of any implement but stone; but iron instruments of indeterminate age have been found, though only just under ground-level. The narrow underground workings are closely packed with stones and mud. It is probable that this was done by the ancient miners for the purpose of concealment, timbering being employed to avoid the necessity of filling the whole stope. The conditions of working the mines must have been so trying, that it is improbable that any but forced labour was employed.

Winter Territory amongst Birds. In the "Calendar of Nature Topics" (Jan. 14, p. 69) it has been pointed out that the winter flocks of crowned sparrows (*Zonotrichia*) seem to keep within territorial boundaries. Observation of another species, the western robin of America (*Turdus migratorius propinquus*), suggests that within the flock there may be individual territory recognised as the exclusive feeding ground of a single bird. John B. Price bases this suggestion upon the movements of two western robins, easily recognisable because of abnormalities in plumage, for otherwise individuals are difficult to observe. These birds appeared to roost nightly with others of their species in enormous flocks (which may number thousands), but during the day they appeared consistently each on its own plot in the campus at Stanford University (*Condor*, 35, 52; 1933). One appeared daily (with three blanks) from January 19 until February 18, 1932; the other from February 12 until 18. The roost from which these daily visits were made was probably four or five miles away, and the regular appearance of the single birds at their own feeding ground (to which they returned before sunrise), their vigorous defence of their plots against new-comers (during a three-minute interval one was seen to join combat ten times) suggest that each western robin in a flock may have its own individual territory during the winter season.

A Virus Disease of Strawberries. The very descriptive name of 'yellow-edge' has been given to a new disease of strawberries ("The Strawberry 'Yellow-edge' Disease" by R. V. Harris, *J. Pomol. and Hort. Sci.*, 11, No. 1, 56–76, March, 1933). The disease is transmissible to healthy plants by grafting, and it is suggested that a virus is the causal agent. The symptoms are a general dwarfing and a malformation of the leaflets, which have chlorotic margins. Petioles lack the normal red pigmentation. Infected plants degenerate in vigour, bear no fruit and ultimately die. Symptoms are apparently masked during the warm period of summer. Control methods are discussed, and the possible identity of the disease with an American disease of strawberries known as 'xanthosis' is indicated.

Batholiths and Ore Deposits. In the *Journal of Geology* for 1933, Prof. W. H. Emmons presents a valuable summary of our present knowledge of the relations between batholiths and the metalliferous veins commonly associated with them. He shows that a normal batholith may be divided into (*a*) the metallised roof; (*b*) the metallised hood, which includes the ore-bearing margin of the igneous mass itself; and (*c*) the core, which is essentially barren of metals. It is believed that the magma of the batholith generated a strong vapour pressure on cooling and crystallising, after the manner illustrated by Morey's experiments on silicate melts. It is probable that this pressure was sufficient to shatter the roofs of some batholiths. Thus the magma may generate the forces responsible for the fractures that later become veins, as well as the metalliferous fluids from which the ores are deposited. The metals were expelled from the magma that formed the core after the hood had solidified. Deposition of ores is believed to have been accomplished before the solidification of the core was completed. Barren veins may form later in the core, but the batholith has now ceased to expel metals. The core appears to be no longer in communication with deep-seated sources of metals, presumably because of relatively early crystallisation at the roots of the batholith.

Flow of Water between Moving Boundaries. Cornish (*Proc. Roy. Soc.*, April) has investigated the flow of water between a revolving brass bush and a coaxial hollow cylinder. The clearance was of the order of 0·1 mm. When the flow was laminar, the resistance was unaffected by rotation at low speeds, but increased when the speed of rotation lay above a critical value. When the flow is turbulent the effect of rotation is found to diminish as the Reynolds' number increases. A set of curves is given which enable practical calculations to be made on flow through annular clearances of this type.

Semi-Conductors in a Magnetic Field. A quantum theory of conduction has been developed by A. H. Wilson (see NATURE, **130**, 913, Dec. 17, 1932). The energy spectrum of the electrons in an atomic lattice splits into a number of bands, which do not overlap in the case of an insulating crystal. If some of these bands are completely filled with electrons, transitions within the band are disallowed by Pauli's principle, and the energy of thermal agitation is insufficient to carry electrons into an upper band. The electrons cannot, therefore, acquire velocities in an electric field and the substance shows no conductivity. Atoms of a suitable impurity may have an energy state only a little below one of the upper unfilled bands, and these electrons may be transferred to the lattice by the effect of thermal agitation. The substance then behaves as a semi-conductor with a conductivity increasing with temperature. Since there are only a few electrons in this upper band, the electron gas is non-degenerate and may be treated by Maxwellian statistics. In a paper by J. W. Harding (*Proc. Roy. Soc.*, April) the effect of a transverse magnetic field on a conductor of this type is calculated. The electrons describe paths under the influence of the applied magnetic field, the applied electric field and the electric field produced by sideways transfer of electrons (Hall effect), together with the collisions with the lattice. An integral equation is set up expressing the condition that the distribution of electrons is steady under these forces. Solving this equation, the currents in different directions are calculated. Different methods are required for weak and for strong magnetic fields. The numerical results are in very reasonable agreement with the shape of the experimental curves for germanium in both strong and weak fields. The absolute value for the change of resistance is nearly right, and the variation with temperature is in the right direction. The Hall effect has not been measured for a semi-conductor but the variation with magnetic field predicted is similar to that observed for bismuth.

Inverse Sublimation. The December 1932 issue of the *Bulletin de la Classe des Sciences* of the Royal Academy of Belgium, which completes vol. 18, contains an interesting communication from M. Octave Dony. M. Dony describes the first of a series of experiments he has undertaken in order to investigate the laws which the crystallisation of a substance from a state of vapour appears to follow. Although this method of crystallisation is of great importance in industry, very little seems to be known as to the circumstances which influence the process. So far, M. Dony has experimented with phthalic anhydride and naphthaline, which were heated electrically in crucibles placed in large rectangular glass enclosures in one case low down, in another half-way up, and in a third near the top. The principal factor in determining the form of the crystals formed is found to be the intensity of the convection currents in the air of the enclosure. In the case of phthalic anhydride, the low position of the crucible tends to produce very long, thin, nearly parallel needles, the central position shorter crossed needles, and the high position very short needles scattered throughout light flocculent masses. There is also an optimum temperature for the crucible.

Radio Telephone Links. A large network of telephones in one part of the world is usually connected with networks in other parts by means of a radio transmission system called a radio telephone link. There are now more than fifty of these links but few of them are working to their full load capacity. The chief problem that has to be considered therefore is that of reducing operating costs. It is only on the few heavily loaded links that the expense of an improvement in the performance of the circuit would be justified. In a paper read to the Institution of Electrical Engineers on May 3, the advantages of using a single side-band system in short-wave telephone links are considered. The chief requirement of a radio-telephone link is that the average ratio of the speech signal to the interfering noises during the conversation must be as high as possible. It must be high enough to give easily intelligible speech over practically the whole period of the advertised service time. The chief advantage of the telephone is its immediate availability at any time required. Even breakdowns for a short period, although only occurring a few times a year, are quite serious. Atmospheric conditions and particularly those accompanying magnetic storms may put a link out of condition for one or two days. It is pointed out that to raise the ratio of the sound signal to the noise signal appreciably would help as the circuit could be kept in constant operation several hours longer although under bad conditions. With our present knowledge, it is impossible to avoid a complete 'fade-out' occasionally. The author gives a full technical discussion of the problem. In particular, he dwells on the many advantages of using short waves and applying the single side-band system to these links. He gives experimental results obtained between stations at Madrid and Paris which bear out his conclusions.

Pelvic Fins of the Lepidosiren

By G. E. H. Foxon, Department of Zoology, University of Glasgow

A REMARKABLE and unique feature of *Lepidosiren paradoxa* is the conversion of the pelvic fin of the male, during the breeding season, into a large gill-like organ. Much confusion exists both as regards the historical development of our knowledge of this phenomenon and also as regards its probable functional significance.

On March 10, 1894, Ehlers[1] pointed out that the pelvic fins of Lepidosiren are sexually dimorphic, those of the adult male being beset along their medio-dorsal surface with a thick growth of flattened papillæ arranged in bunches springing from a common base. Over the date March 20, 1894, Lankester[2] recorded and illustrated the same structures, and remarked that "whether tactile or respiratory they form a most remarkable feature". On June 19, 1894, Lankester[3] again figured the papillæ and, after examining them in microscopic section, suggested the possibility of their being erectile and of copulatory significance.

The discovery that the papillæ observed by Ehlers and Lankester are merely dormant rudiments which undergo active growth in relation to the breeding season was made by Prof. Graham Kerr on November 4, 1896; his diary referring to eight captured Lepidosirens contains the note, "Of these, two males appear to be assuming nuptial dress. The lateral papillæ which Lankester described are represented by branched filaments forming a thick fringe. Highly vascular and deep red in colour". On November 8 he recorded a female with rudimentary villi. A note written by Prof. Kerr during his stay in the Chaco but undated reads: "In many cases the fore limb is flattened and bears on its lower edge a series of flat papillary processes,—a rudimentary fringe. The fringe seems prominent in several males where fringe on hind limb: is there any connection between the two ?"

In his first paper on the Lepidosiren, Prof. Kerr[4] merely suggests that the fringes in question are nuptial developments comparable with those occurring not uncommonly in fishes and amphibians. In later papers, however, he shows himself more and more firmly convinced that the true physiological function of the filaments is as accessory organs of respiration, of special value to the male Lepidosiren which remains on guard over the eggs deposited in the burrow, as lessening the need of his temporarily leaving his charge unprotected in order to proceed to the surface to fill his lungs with air. Prof. Kerr indeed has a footnote to this effect in his first paper.

Agar[5] has added to our knowledge of these filaments and he was the first to describe those cases in which the pectoral fin shows similar developments to those of the pelvic fin. He also notes that the process of atrophy of the filaments coincides with the end of the period during which the male is guarding the young in the nest.

The possibility that the function of the filaments is connected with the emission of oxygen for the respiration of the eggs makes its first appearance in a paper by Budgett[6] published in August 1901. Budgett, who had been Prof. Graham Kerr's companion in the Chaco, and had intimate first-hand knowledge of the Lepidosiren and its habits, writes: "It is tempting to regard the vascular fringes on the pelvic limbs of *Lepidosiren* as in some way connected with the aeration of the eggs". Although mentioning the idea in print, Budgett with his practical knowledge did not adhere to it, but concluded that, "it seems more probable that the fringes are as Kerr holds, accessory organs of respiration".

Mr. J. T. Cunningham[7] in 1912 repeats Budgett's earlier suggestion: "it would seem more probable that the use of the filaments in the Lepidosiren is to provide for the respiration, not of the parent himself, but of the ova".

Dr. Carter and Mr. Beadle[8] in carrying out their investigations in the Chaco developed quite independently a distinct leaning towards the emissive significance of the filaments. The revival of interest in the 'emissive' hypothesis is due to the publication of two papers, by Cunningham[9] and by Cunningham and Reid[10] respectively. The first of these is mostly speculative and will not be referred to further, except to note that the statement that the filaments arise from the ventral side of the fin, instead of as described by Ehlers, Lankester and Graham Kerr, is incorrect. In the second paper, however, Mr. Cunningham and Mr. Reid support the emissive hypothesis by actual observations carried out on the Island of Marajo.

Before proceeding to indicate why the experiments of Cunningham and Reid are insufficient to prove that the function of the pelvic filaments is to emit oxygen, it will be as well to summarise why the probabilities lie in the opposite direction, that is, that under natural conditions the filaments are concerned with the respiration of the parent.

The nests lie at the bottom of the swamp; they are very variable in size, but generally extend for several feet horizontally, being about nine inches to one foot in diameter. The eggs are scattered at random in a single layer over the floor of the burrow, and it may be pointed out that the smooth surface of the egg-shells makes it physically impossible for them to be piled up in a heap round which the parent could lie coiled up. The suggestion that the filaments emit oxygen in the immediate neighbourhood of a pile of eggs or a mass of larvæ is not, therefore, consistent with the facts; and to raise the oxygen content of the water sufficiently to be of use to the developing young it would have to be raised throughout the burrow. In a burrow 2 ft. 6 in. long with a diameter of 9 in. the oxygen content of approximately 31 litres of water would have to be raised.

The nest lying at the bottom of the swamp, any breathing on the part of the male would, as Budgett pointed out, necessitate a journey through several feet of water to the surface. The male guards the nest, frequent absences would give opportunities for enemies to enter and make a meal off the eggs or young larvæ, and frequent coming and going would only serve to attract attention to the presence of the nest. Again, the vascular filaments themselves would be a juicy morsel for any enemy, and if they were lost in this manner, severe and probably fatal bleeding would result. Repeated excursions to the surface such as would have to be made if the male were in any way a means of supplying oxygen to the young, would be seriously detrimental to the welfare both of the male and to the offspring. It is entirely reasonable, therefore, to regard the filaments as a means of diminishing the need of frequent absences from the nest.

The positive evidence adduced by Cunningham and Reid in support of the 'emissive' function is merely that in certain cases the amount of oxygen in water of low oxygen content is increased when a Lepidosiren with pelvic filaments is placed in it. That this is so is only to be expected, seeing that the fish had access to the air and were allowed to breathe at intervals throughout the experiments. It would be more remarkable if the oxygen content of the water did not rise, for Mr. Cunningham[9] himself has shown that in de-oxygenated water goldfish, perch and axolotls all allowed measurable quantities of oxygen to leak away. That oxygen is not given off by female Lepidosirens or by immature males is no doubt due to the epidermis not being thin enough to allow such diffusion to take place—even the gills are too thick (Fullarton[11])—while on the other hand the breeding male, in the pelvic filaments, possesses an organ through which such diffusion can take place. If a male Lepidosiren, with filaments, is submerged in de-oxygenated water but is allowed to keep up the oxygen tension in its blood by breathing air into its lungs, a rise in the oxygen content of the water is only what is to be expected.

Before reliable conclusions can be reached, information must be sought as to what happens when males with filaments are denied access to atmospheric oxygen. Prof. Graham Kerr found that Lepidosirens, if prevented from breathing air, quickly die; an instructive and perhaps conclusive experiment could be performed if the times taken by ordinary male Lepidosirens to drown were compared with those taken by males with filaments. If the 'emissive' hypothesis is correct then the breeding males must die more quickly than the others.

Finally, it should be borne in mind that in all cases where oxygen is actually excreted from the blood, as in the air-bladders of certain fish, glands for that purpose are present; in the Lepidosiren no such structural modifications have been described.

Metals and Man*

THE first annual Research and Development lecture arranged by the British Science Guild was delivered, on May 16, in the hall of the Carpenters' Company, London, by Sir Harold Carpenter, his subject being "Metals in the Service of Human Life and Industry". Lord Melchett, who presided, said that the lecture had been instituted to direct attention to the importance of research—both purely scientific and technical—and the utilisation of its results for the benefit of mankind. The British Science Guild desired the lecture to be associated with the name of Sir Richard Gregory, who as Editor of NATURE, and in other activities, had done so much to secure increased recognition of the services rendered by science and scientific workers to progressive life.

Sir Harold Carpenter began his lecture by pointing out that, of the products of the physical universe which have contributed most to the comfort of the human race and the industrial progress of the world, metals are entitled to the first place. Man's most striking achievements have depended largely on the use of metals, as indicated by ships, bridges, railways, automobiles, power stations, aeroplanes, telegraph and telephone systems and broadcasting.

Leaving agriculture and fishing out of consideration, the beginning of metallurgy was the beginning of industry and also the beginning of civilisation. The material achievements of metallurgy constitute only a portion of its service to mankind, as it was in the practice of this art that man developed mental attributes which led to the foundation of science and modern thought. From the practice of this art men acquired the mental habit of inquiring into the phenomena observed in order to attain control over them and thus over Nature also. Chemistry developed from the old art of metallurgy, but engineering did not do so; yet in recent years the engineering, chemical, and metallurgical industries have reacted on each other in innumerable ways.

The core of the earth probably consists mainly of an alloy of iron and nickel, but the crust is of an entirely different composition. This crust has resulted from the gradual solidification of the earth from the state of a molten ball. During this solidification a sorting out of constituents has taken place, resulting in a layer of silicates on the surface containing originally very little metal, but during further cooling a differentiation of the constituents has taken place resulting in the separation of silicates and sulphides and the concentration of metals in certain parts.

The calculated composition of the accessible crust indicates that, of the metals, only aluminium and iron are present in appreciable amounts, and that all other metals taken together amount to less than half of one per cent. If these metals were uniformly distributed, metallurgy would not exist. The concentration of the metals in workable deposits in relation to concentration in the earth's crust varies from 4 to 5 times in the case of aluminium, to 4,000 to 15,000 times in the case of silver.

From the point of view of the rise and development of the metal arts from the earliest times, the industrial history of mankind may be divided into two major epochs—a stone age and a metal age. Between these there was a transitional period in which the metals, as found in their native state, were used as stones. The definite establishment of a metal age was due mainly to the discovery of the possibility of smelting metals from stones, and the importance of this discovery comes in the same category as the first method of producing fire artificially.

The metals gold and copper were the first to be used by man, and both were obtained from native metals. From the mere melting of a native metal to the smelting of an ore was a great advance, and this discovery was, in all probability, the result of an accident at the edge of a camp fire. The observation by the early workers that copper, as obtained from different deposits, had different properties, led to the mixing of other materials with the copper ore being smelted and ultimately to the production of bronze. It is generally recognised that so early as 3000 B.C., the Egyptians were skilled in the smelting and casting of copper, but the earliest authentic bronzes date from about 1600 B.C.

---

* "Metals in the Service of Human Life and Industry". Pp. 39. British Science Guild, 6, John Street, Adelphi, W.C.2. 1s., including postage, 1s. 1*d*.

The next important discovery was the production of iron, and it is generally agreed that iron did not come into general use in Egypt until 1300 B.C., which may be taken as the beginning of the iron age. It appears that the Egyptians were acquainted with the carburising process for converting iron into steel about 1200 B.C., and with the quenching process for hardening steel about 900 B.C. After this, no important metallurgical discovery appears to have been made for a long time. Brass was first made at the beginning of the Christian era, and the next discovery of prime importance was that of cast iron, which was first made in the fourteenth century. This discovery was the outcome of the gradually increasing size of the furnaces used for making direct iron. The smelting of iron ores in large furnaces with the use of coke began early in the eighteenth century and marks the beginning of the modern iron and steel industry.

The next discovery of importance was the making of crucible steel at the end of the eighteenth century, but steel did not become available in large quantities until the invention of the Bessemer process in 1856. During the last seventy-five years the development has been rapid and during the past thirty years more metal has been used than in all previous time.

Sir Harold Carpenter traced the progress of casting metal from the first castings in stone moulds to the modern methods of centrifugal and pressure die castings. The properties of metals, including strength, ductility and malleability received attention, and the chemical properties, especially as regards their resistance to the chemical action of their environment during service, that is, corrosion, were shown to be of the highest importance.

The effects of science on metallurgy have been most marked and important. So recently as just over a century ago, changes in metallurgical practice were mainly the result of chance discoveries or the consequence of a reaction to changing economic conditions. Scientific attention began to be directed to the systematic search for new alloys, new methods of mechanical and heat treatment, more economical methods of manufacture, better plant and greater reliability of product. The most conspicuous illustration of the influence of science on metallurgy is found in the case of aluminium. It is the most plentifully occurring metal in the earth's crust and yet has become available only within living memory. To-day, iron and aluminium are the two most important metals, iron having been used by man for over three thousand years and aluminium for under fifty years. The application of the methods of science to the ancient art of metallurgy, and the increased knowledge gained thereby, will contribute ever increasingly to the amenities of human life and the progress of art and industry.

Spectra of the Planets

THE annual George Darwin lecture was delivered at the Royal Astronomical Society's meeting on May 12; the lecturer being Prof. V. M. Slipher, director of the Lowell Observatory. He chose as his subject the spectra of the planets, the study of which has been, from the first, an important feature in the work of the Lowell Observatory. He noted that the advent of the spectroscope made it possible to learn something about the chemical composition of other worlds, and gave a sketch of the early work carried out by Sir William Huggins, using visual methods.

The introduction of photographic methods made a great advance possible; when the method was first used, the plates employed were insensitive to red light, and the infra-red region was quite excluded. Of late, the makers of plates have triumphed over these difficulties, and a great extent of the infra-red spectrum can now be photographed. This is specially important in planetary work, as there are many interesting lines and bands in this region.

An initial difficulty is that of separating planetary lines from those due to the terrestrial atmosphere. Prof. Slipher described different methods of discrimination; comparing a planet with the moon at the same altitude, or comparing the planet's spectrum at high and low altitudes. Also the terrestrial lines can be weakened by going to a high station. Some photographs have been taken at the San Francisco Peak, 11,000 ft. high, which is near the Observatory.

Another method, needing considerable dispersion, makes use of the shift of the planetary lines due to radial motion. This has been applied to Venus, with the result that oxygen cannot be traced in its spectrum, but carbon dioxide is suspected. Great endeavours were made to test the rotation of Venus by the spectroscope. The slit was placed in various position angles, also with the spectroscope in two opposite positions, 180° apart; the plates were shuffled, and the measurer kept in ignorance of the conditions of exposure, to prevent any possible bias. Unfortunately, no positive result was reached, but Prof. Slipher considers that ten days might be named as a lower limit to the planet's period of rotation.

Some twenty-five years ago there was a controversy as to the presence of the *a* band, due to water vapour, in the spectrum of Mars. Lowell's book on the planet, published in 1909, included a reproduction of spectra taken by Prof. Slipher in 1908, showing the *a* band stronger in the Martian spectrum than in the lunar one. Some doubt was thrown on this by other observers, but the presence of a small amount of water vapour is now generally accepted.

Prof. Slipher then proceeded to discuss the four giant planets; their spectra resemble each other in showing series of conspicuous bands, which increase in strength as we go from Jupiter to Neptune. Spectrograms of Jupiter were shown, which exhibited bands far in the infra-red, to wave-length 10,000, but 8,600 was the limit reached in the case of Uranus and Neptune. The origin of most of these bands is still unknown, but lines due to ammonia have lately been identified in the spectrum of Jupiter; a slide was shown in which they were visible. It is appropriate finding ammonia in Jupiter, as the name is taken from the temple of Jupiter Ammon in Africa, which appears to have been the earliest source of supply of this substance.

Allusion was next made to the determination of the period of rotation of Uranus by spectrograms taken at the Lowell Observatory in 1911. The equivalent focus used was 55 ft., and the usual precaution was taken of rotating the spectrograph through 180°, between two series of exposures. The deduced time of rotation was 10·7 hours. Some attempts are being made to see if Pluto shows any periodic variation of light, from which its rotation time can be deduced; but there is nothing as yet to report.

The suggestion, now generally accepted, that the stationary calcium lines in certain stellar spectra are due to light-absorption in interstellar space, not in the stars themselves, was made at the Lowell Observatory in 1909. Prof. Slipher spoke of some faint lines that were photographed on the dark side of Venus, but he is inclined to ascribe them to our own atmosphere. He expressed the opinion that there is a faint permanent aurora present in the atmosphere, and showed some plates taken with long exposures, on which the auroral lines could be traced.

At the conclusion of the lecture, the president, Prof. F. J. M. Stratton, presented the gold medal awarded by the Council to Prof. Slipher for his spectroscopic work on planets and nebulæ. He said that the lecture itself sufficiently established the grounds for the award, and dispensed with the necessity of a presidential address on the subject.

The 'Catkin' Radio Valve

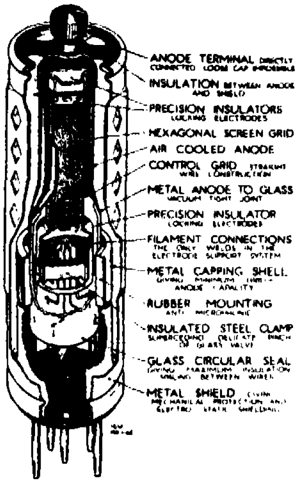
WITH the rapid growth in broadcast reception, the general public has become used to frequent changes in the types and design of receiving valves. These new types have usually been aimed at giving improved performance under modern conditions of radio communication, and in the past, they have invariably appeared in the familiar glass bulb form. A radically different type of construction is adopted in the 'Catkin' valve, which was placed on the market on May 18, by the General Electric Co., Ltd. and the Marconiphone Co., Ltd. This new valve is really a small model of the high-power type of 'Cooled-Anode-Transmitting' (C.A.T.) valve which was produced for wireless transmitting stations a few years ago.

In the new construction shown in the accompanying sectional diagram (Fig. 1), the amount of glass-work, with its fragility and dielectric losses, has been reduced to a minimum. The upper portion of the envelope is formed of the cylindrical copper anode which is sealed to the lower glass portion by a vacuum-tight joint. The other electrodes are rigidly mounted inside this envelope, using mica spacing and insulating pieces where necessary. In the glass type of valve the electrode system is usually carried in the glass 'pinch' near the base, an arrangement which makes it difficult to ensure definite location and gives rise to considerable dielectric losses in some valve circuits. In the new construction, the lower ends of the electrodes are held rigidly in a suitable steel clamp with mica insulation, and the leads are brought out through the glass ring at the base, being well spaced around its circumference. This arrangement makes it possible to obtain much greater precision in the electrode dimensions and spacing in manufacture, so that the mass-produced valves should conform much more accurately to a uniform performance than was possible hitherto.

The glass ring forming the lower portion of the envelope is supported in its base by a rubber clamp, which acts as an efficient sound insulator, thus reducing the susceptibility of the valve to microphonic effects. The much smaller diameter of the anode also results in comparative freedom from response to sound vibrations transmitted through the air, which sometimes form a source of trouble with glass valves.

Screen-grid and detector valves are, nowadays, usually metallised in order to avoid the effects of strong electric fields set up by charges on the glass envelope. The electric field within the anode of the Catkin valve is entirely uninfluenced by any surrounding charges. If further screening is required in order to reduce stray coupling to the anode itself, an octagonal tubular metal cover is provided fitting over the entire valve. In this form the valve is remarkably strong mechanically and its overall *dimensions, including the standard four- or five-pin* cap, are about 5 in. by 1⅛ in. diameter.

Output valves do not require this outer screening cover, and in this case the exposed anode is given a coating of black enamel insulation. In all cases, since the anode is exposed directly to the air, liberal heat-dissipation is provided and the electrode system as a whole runs at a lower temperature, thus reducing the liability of the valve to soften due to the release of gases occluded on the inner walls of the envelope.



ANODE TERMINAL DIRECTLY CONNECTED
INSULATION BETWEEN ANODE AND SHIELD
PRECISION INSULATORS LOCKING ELECTRODES
HEXAGONAL SCREEN GRID
AIR COOLED ANODE
CONTROL GRID STRAIGHT WIRE CONSTRUCTION
METAL ANODE TO GLASS VACUUM TIGHT JOINT
PRECISION INSULATOR LOCKING ELECTRODES
FILAMENT CONNECTIONS THE ONLY WELDS IN THE ELECTRODE SUPPORT SYSTEM
METAL CAPPING SHELL GIVING MINIMUM ANODE CAPACITY
RUBBER MOUNTING ANTI MICROPHONIC
INSULATED STEEL CLAMP SUPERCEDING DELICATE PINCH OF GLASS VALVE
GLASS CIRCULAR SEAL GIVING MAXIMUM INSULATION BETWEEN WIRES
METAL SHIELD GIVING MECHANICAL PROTECTION AND ELECTRO STATIC SHIELDING

FIG. 1.

The Catkin valve is at present being supplied in four types, the constants of which are similar to those of the corresponding glass valves, so that they are interchangeable with those in use in present-day receivers.

University and Educational Intelligence

BIRMINGHAM.—Shortly after the death of Prof. John Henry Poynting in 1914 a fund was subscribed by his friends with the object of providing a memorial to him. Part of the money thus raised was used for the publication (by the Cambridge University Press) of a volume of his "Collected Scientific Papers", of which a copy was presented to every university in the British Empire and to representative universities in foreign countries. Another part of the fund was used for the purchase of a portrait to be presented to the University of Birmingham and hung in the great hall of the University. The remainder, which was invested, together with the accrued interest, has been offered to, and accepted by, the Council of the University, for the foundation of a Poynting lecture, to be delivered at intervals of not more than two years by physicists of outstanding distinction.

CAMBRIDGE.—The Adams prize for 1931–32 has been awarded to A. H. Wilson, research fellow of Emmanuel College.

The managers of the Balfour Fund have made grants of £50 to Mr. C. Forster-Cooper, of Trinity Hall, for researches on the fauna of the Achenarass quarries and to I. T. Sanderson, of Trinity College, for researches on the vertebrate fauna of the Cameroons.

It is recommended by the General Board that a readership in physiology be established with a pensionable stipend of £850, and that the first holder of the readership be Dr. F. R. Winton, of Clare College, at present University lecturer in physiology.

It is recommended that an additional University lectureship and an additional University demonstratorship be established in the Department of Anatomy.

The degree of Sc.D., *honoris causa*, is to be conferred on the Marchese G. Marconi, and on Sir Frederick Gowland Hopkins, Trinity College, Sir William Dunn professor of biochemistry.

At Clare College, H. McC. Taylor has been elected to a research fellowship. Mr. Taylor was a wrangler (*B**) in the Mathematical Tripos Part II, 1930 and was elected to a Smith's prize and to an Allen scholarship in March 1932.

SHEFFIELD.—At a meeting of the Council, held on May 12, the following appointments were made: Dr. G. A. Clark, at present lecturer in physiology, to the chair of physiology, in succession to Prof. J. B. Leathes; Mr. W. R. Maddocks, as lecturer in metallurgy; Mr. J. Dick, as assistant lecturer in mechanical engineering; Mr. A. J. Macdougall, as assistant lecturer in metallurgy.

WALES.—Dr. W. R. Ivimey-Cook has been appointed assistant lecturer and demonstrator in botany in University College, Cardiff.

The University of London's activities during 1932–33, as reviewed in the Principal's report, presented on May 10, showed steady progress despite the necessity laid upon it in common with all other institutions in the country of exercising the utmost care in husbanding its resources. The Bloomsbury site figures prominently in the report. The general design for the whole site was completed by the architect, Mr. Holden, and exhibited in the form of a sketch model. Building is to begin at the southern end, next to the British Museum, the material employed being Portland stone with a brick core. The foundation stone is to be laid on June 26 by H.M. the King. In this connexion an outstanding event of the year was the gift of £100,000 by the Corporation of the City of London towards the cost of a new Ceremonial Hall, and this gift was followed by others toward the same purpose by many other City companies, the aggregate total to date being £166,000. In a long list of other important benefactions, including £48,000 from the Rockefeller Foundation for the endowment of clinical research in connexion with University College Hospital and the Medical School, an interesting item is the gift by the editor and proprietor, Dr. William Page, of the copyright and material of the "Victoria County History" of which ninety-one volumes have already been issued and as many more are projected. The Pilgrim Trust has granted the University £1,500 towards the cost of completion. The total admissions to the University in 1932–33 were 11,891 as compared with 6,295 in the first year after the War and 11,018 in 1931. The roll of internal students comprises 12,219 names, an increase of 529 compared with the preceding year, while those registered as external students have been steadily maintained at about 13,000.

AMONG the awards of Commonwealth Fund fellowships tenable by British graduates in American universities for the two years beginning September 1933 are the following: Mr. J. W. L. Adams (Oxford) to the University of Chicago, in economics; Mr. J. F. Danielli (University College, London) to Princeton University, in Chemistry; Mr. J. E. Harris (London and Cambridge) to Columbia University, in zoology; Mr. S. H. Jones (Swansea) to Johns Hopkins University, in geology; Mr. B. B. Kinsey (Cambridge) to the University of California, in physics; Dr. J. H. Lamble (Liverpool) to the University of Michigan, in engineering; Dr. Andrew McLean (Edinburgh) to the University of Illinois, in chemistry; Mr. C. E. Marshall (Durham) to the University of Pittsburg, in geology; Mr. H. S. A. Potter (Oxford) to Princeton University, in mathematics; Mr. E. A. Radice (Oxford) to Columbia University, in economics; Dr. H. C. Rowan (Birmingham) to the Massachusetts Institute of Technology, in engineering; Dr. J. C. E. Simpson (Liverpool) to the Rockefeller Institute, in chemistry; Miss P. M. Skinner (Cambridge) to the University of Wisconsin, in mathematics; Mr. R. H. Stoy (Cambridge) to the University of California, in solar physics; Mr. I. W. Tervet (Glasgow) to the University of Minnesota, in botany; Mr. E. L. Trist (Cambridge) to Yale University, in psychology. Mr. G. G. Cillié (Stellenbosch and Oxford) has been awarded a Dominion fellowship, for astrophysics, and will go to Harvard University. The following have been appointed to fellowships tenable by candidates holding appointments in government service overseas: Dr. C. M. Focken (Melbourne and Oxford), of the Department of Education, Government of New Zealand, to the Colorado School of Mines, in engineering; Dr. H. W. Mulligan (Aberdeen), of the Indian Medical Service, to the University of Chicago, in medicine; Mr. R. McI. Tyndale-Briscoe (Cambridge), of the Department of Mines and Public Works, Government of Southern Rhodesia, to Harvard University, in geology.

Calendar of Nature Topics

Weeds

The unceasing battle against weeds has now reached the spring phase, when the innumerable seedlings breaking through the newly-drilled cornfields and root breaks are receiving special attention. The aim is to disturb and weaken as many weeds as possible in the hope that the crop will master the remainder. Light harrows are used, and, even if some corn is uprooted or potato sprouts knocked off, the loss is more than compensated by the cleaner crop. In the corn crops little further is done, for horse-hoeing between the narrow rows of cereals, one of the most skilled and exacting jobs of the agricultural worker, is now seldom practised. In roots, the struggle continues until the plants meet in the rows.

Although hoes and harrows have been increased in size and improved in design, no alternative to the mechanical treatment of weeds is yet in general use. Two new methods of approach have been tried and are making headway. The best known consists in spraying the weeds in the standing crop of corn with corrosive solutions or dusts. The success of these methods depends on the fact that the upright, waxy leaves of the corn are much less damaged than the flat leaves of the infesting weeds. Another possibility is the use of stronger doses of more toxic compounds when the ground is unoccupied by a crop. The problem here is to discover a substance that is cheap enough to use on an acre scale. It must also decompose in the soil to leave the land fit to be cropped at the proper time.

The extension and perfecting of weed control by chemical means is highly desirable, but it must not be overlooked that certain indirect benefits accrue to the cultivator by his mechanical efforts against weeds. The soil is maintained in a well-aerated and crumbly condition, the loss of water is reduced, and active production of nitrates is encouraged. The value of these conditions is difficult to assess, but something would have to be done to attain them in any event. The farmer's best ally in his cleaning operations is a dry season. The extraordinary summers of 1911 and 1921 enabled some of the most obstinate land to be set in order. But success is never complete; dormant weed seeds resist all efforts to make them germinate, and survive to open a fresh attack at some later season.

Kangaroo Mouse of Western America

In the high grounds of Nevada, Oregon and California, at an altitude of 4,000–6,000 ft., lives "one of the most remarkable of the many new and interesting mammals that have been discovered in North America during the past few years", the kangaroo mouse (*Microdipodops megacephalus*). Probably the newly born young have never been seen in the nest, but the discovery of pregnant females in Nevada by E. Raymond Hall and Jean M. Linsdale showed that the breeding season reached its climax in May and early June and tailed off in July. The young are relatively large at birth and number one to six in a litter (*J. Mammalogy*, 10, 298; 1929). The mice, six inches in length, progress rapidly by hopping along on their hind feet, and so great is the power and accuracy of their jumping that a young individual repeatedly leapt out of a can, ten inches in diameter and seventeen inches high, without touching the sides of the can. During the day, kangaroo mice live in burrows excavated in fine sand, and the entrances to these they appear to block with sand when they enter them in the morning, so that they become invisible. Whenever an open burrow was discovered it was empty. The habit of living in loose fine sand results in spotted distribution where the type of soil varies markedly, and the distribution is further restricted because of the need of plants yielding the seeds which probably form the main part of the diet of the mice.

Phæocystis and Herrings

Usually in May the sea becomes a brownish-green colour in patches owing to the presence of the colonial flagellate *Phæocystis*. On examination, this organism is found to exist in the form of spherical gelatinous masses containing numerous small greenish-brown cells. Later on, these balls of cells become sausage-shaped. Multiplication is very rapid, and at this season naturalists' tow-nets become so clogged up with *Phæocystis* that all the catches are spoiled. Its maximum occurs between the end of April and the beginning of June but there may be a secondary maximum in autumn. At Plymouth it appears regularly—nearly always in May—stays for a few weeks, and then disappears.

Water coloured by *Phæocystis* or diatoms has been given many names by fishermen in different places, such as 'weedy water', 'stinking water', and 'baccy juice'. It has been shown that the presence of *Phæocystis* in the North Sea may have an important effect on the herring fishery. Herring avoid a large mass of this 'coloured water' and will make a wide detour rather than go through it. In this way the shoals of fish may sometimes be deflected from their normal haunts and turn up in some other place where unexpectedly good catches will result while poor catches are obtained on the usual and generally highly productive fishing grounds.

Societies and Academies

LONDON

Royal Meteorological Society, April 26. C. S. DURST: The intrusion of air into anticyclones. An examination of the dynamical equations of a rotating fluid on a rotating globe shows that the descent of air in an anticyclone will cause an inflow towards the centre of the right order of magnitude to balance the outflow of air due to friction near the surface. An explanation is given of the empirical forecasting rule that warm-cored anticyclones are likely to endure. H. M. VERNON: The estimation of solar radiation in relation to its warming effect on the human body. The globe thermometers described consist of globes of copper, glass or pasteboard, painted black or covered with cloth, and with an ordinary thermometer fixed so as to have its bulb in the centre. Up to a certain point, the larger the size of such globes the higher the temperature indicated on exposure to solar radiation, but the limit is practically reached with globes 6–9 in. in diameter. The temperature then indicated corresponds with the warming effect of the solar radiation on the human body. Globe thermometers are considerably influenced by wind velocity. J. GLASSPOOLE: The rainfall over the British Isles of each of the eleven decades during the period 1820 to 1929. Maps are given defining the rainfall experienced over the British Isles during each of the eleven decades 1820–29 to 1920–29. The rainfall of each locality is given as a percentage of that for the standard period 1881–1915, so that each map presents a fairly simple distribution. The main feature of the distribution of rainfall during the decade 1920–29 was that excesses were most marked in the west of Great Britain, while during the decade 1910–19 the excesses were most marked in the south of England.

Geological Society, March 22. W. Wickham King: The Downtonian and Dittonian of Great Britain and north-west Europe. The discovery of a shell fauna (seven genera) and a gastropod in stages I. 5 to I. 9 of the English Downtonian series is described. The fishes and crustaceans known in the British Silurian rocks, and the fauna common to the Downtonian and Dittonian series, are set out. These, when combined with an examination of the physical conditions in the Siluro-Devonian period, afford a solution of the problem of the boundary between these two systems which is in agreement with the views of Norwegian geologists in relation to the Red Bay series of Spitsbergen. F. R. Cowper Reed: Downtonian fossils from the Anglo-Welsh area.

Dublin

Royal Irish Academy, Feb. 27. R. W. Ditchburn: The transmission of resonance radiation through a gas. In the first section the problem is formally reduced to a problem of transmission by absorption and scattering (as in a 'foggy' atmosphere). In the second section two general equations for this type of transmission are deduced. The relation $\nabla^2 E = K E$ (where E is the radiation density and K is constant) is shown not to be true. In the third section two special cases are considered: (*a*) transmission outwards from the centre of a sphere: (*b*) transmission outwards from the centre of a long cylinder.

Paris

Academy of Sciences, April 3 (*C.R.*, 196, 973–1056). Camille Matignon, Henri Moureu and Maurice Dodé: The causes of the simultaneous production of 1-butene and 2-butene in the course of the catalytic dehydration of butyl alcohol by alumina. The variations in the proportions of the two isomeric butenes obtained in this catalytic reaction have been traced to the presence of impurities in the alumina. Traces of acid favour the production of the 2-butene. J. Cabannes: The depolarisation of diffused light by a uniaxial crystal when the optic axis is parallel to the diffused ray. Experimental study and theoretical considerations. Jean Baptiste Senderens: The catalytic decomposition, in the gas phase, of the esters of the fatty acids by sulphuric acid pumice. Jules Haag was elected *Correspondant* for the Section of Mechanics, Gustave Binger for the Section of Geography and Navigation and Henri Devaux for the Section of Botany. Serge Finikoff: Surfaces the lines of curvature of which correspond with equality of the principal homologous radii of curvature. St. Golab: The conformal representation of two Finsler spaces. Soula: An integral equation. A. Tsortsis: The integration of a class of linear partial differential equations of the second order with an unknown function of n independent variables. Henri Cartan: Groups of pseudo-conformal transformations. Torsten Carleman: A differential inequality in the theory of analytical functions. F. E. Myard: An absolutely general linkage between any two axes of rotation in space. A. Magnan: The optical determination of the direction of threads of air in motion. Jean Baurand: Periodic progressive waves at the surface of a basin of small depth. P. Dumanois: Concerning the classification of liquid combustibles for internal combustion motors, with mechanical injection. Emile Sevin: The absorption of the cosmic radiation by the atmosphere. F. Prunier: Concerning the equations of electromagnetism. J. Granier: The conducting properties of india-rubber heavily loaded with lamp black. Vulcanised rubber containing 50 per cent of lamp black acts as a conductor for alternating currents and this conductivity appears to be electronic as it is not a function of the time and the electrodes show no trace of corrosion. The resistance varies with the pressure and various applications of this property are suggested. J. Lecomte: The infrared absorption spectra of some halogen derivatives of methane, studied with a recording spectrometer. A new type of instrument is described in which the photographic paper is fixed: the only moving part is the prism with an attached mirror. Data are given for eleven halogen derivatives of methane. P. Fleury and G. A. Boutry. The exact measurement of photographic densities. Use is made of a photoelectric cell working at constant deviation, thus eliminating the phenomena of lag and hysteresis. The negative (of density X) and a wedge (of variable density D) are superposed, realising the condition $X+D=\text{constant}$. The accuracy obtained is of the order of 0·1 per cent. F. Bourion, E. Rouyer and Mlle. O. Hun: The cryoscopic determination of the hydration of ions in solution. Jean Cournot and Mlle. Louise Halm: The measurement of the degree of polishing in view of the determination of the amount of corrosion of rustless steels. It has been shown that in studying the corrosion of chrome-nickel rustless steels the exact condition of the surface must be capable of definition. An apparatus based on the use of a photoelectric cell is described which has given satisfactory results. Augustin Boutaric and Mlle. Madeleine Roy: The influence of radioactive radiations on the flocculation of colloids. The experiments described clearly establish that the sensibility of the flocculation to the action of the radioactive radiation does not depend on the chemical constitution of the granules but only on their electric sign. Pierre Süe: The determination of niobium by orthoxyquinoline. Under conditions detailed, niobium pentoxide forms a microcrystalline precipitate with orthoxyquinoline: the niobium thus separated can be determined either gravimetrically or volumetrically. Guichard: Remarks on the atomic weight of iodine. The author gives reasons for preferring 126·91 to the International Commission figure, 126·932 and maintains the trustworthiness of direct determinations based on the use of iodine pentoxide. A. Tchakirian: The preparation of germanous iodide and the action of silver nitrate on the halogen derivatives of methane. Guy Emschwiller: The action of gaseous hydrogen iodide on some iodine derivatives of hydrocarbons: new methods of preparation of ethylidene iodide, vinyl iodide and methyliodoform. The reactions of gaseous hydrogen iodide with organic iodine compounds differ from those of aqueous hydriodic acid. Some new reactions are described leading to the preparation with good yields of ethylidene iodide, vinyl iodide and methyliodoform. Martin Battegay and Elsayed Hégazi : The chloride of thiourea, chloride of thionecarbamic acid or thiocarbamyl chloride. Raymond Furon : New observations on the extension of the Cretaceous and of the Eocene in the Niger Colony. D. Schneegans and G. Emilianoff : The presence of Tertiary strata in the Gabon basin (French Equatorial Africa). Pierre Urbain : The relative impermeability of the plastic sediments towards rain water, spring water and various alkaline solutions. Clays or marls may be impermeable to rain water and very permeable to spring water: hence the term impermeability has only a relative significance. Nicolas Menchikoff : The Devonian of Menakeb (Western Sahara). Georges and Boris Choubert : New tectonic observations on the Tabor massif. H. Colin and J. Augier : The soluble glycides of *Lemanea nodosa*. Floridoside and trehalose have been isolated from this alga. Muller and Desmarez : The differential microscopic characters of the bone of adult *Cynocephalus* and of human bone. It has been generally assumed that it is difficult, if not impossible, to differentiate the bone of the ape from human bone. The bones of the baboon, however, show characters clearly different from those of man. Abel Desjardins : The whirling vibrations of the organism. Eugène Donard and Henri Labbé : The co-existence in the rootlets of barley of hyperglycemiant and hypoglycemiant bodies. André Pacaud : An attempt at raising *Simodaphnia* and *Moina* in a synthetic medium. R. Guillemet and C. Schell : The sulphur of wheat, its nature and distribution. Correlation between the ratio of sulphur to nitrogen in wheat and the baking value of the flour. Gaston Ménier : Researches on the purification of air. A purifying apparatus.

Washington, D.C.

National Academy of Sciences (*Proc.*, 19, 1–207, Jan. 15, 1933). Albert Ernest Jenks : Minnesota Pleistocene *Homo*—an interim communication. On June 16, 1931, a skeleton was found in constructing a new road some three miles north of Pelican Rapids, in Pelican township of Ottertail county, Minnesota. The site showed no signs of a burial and was in laminated silt in the bed of a glacial lake (Glacial Lake Pelican). The skeleton is practically complete, possibly that of a woman aged seventeen years. The skull is that of an early form of *Homo sapiens*, of a generalised Mongoloid type, but shows noteworthy peculiarities. The skeleton was in sediment of late Pleistocene origin and has been named 'Minnesota man'. Photographs are reproduced. C. Judson Herrick : The functions of the olfactory parts of the cerebral cortex. In primitive types the olfactory system is the dominant feature of the cerebral cortex but in primates it is reduced to a subordinate position. At all stages of cortical differentiation, an important function of the olfactory cortex is to serve as a non-specific activator for all cortical activities. G. Karl Huber and Elizabeth C. Crosby : A phylogenetic consideration of the optic tectum. The tectum reaches its greatest morphological development in the reptiles and birds ; in mammals, the sensory centres of the cerebral cortex have taken its place as the major sensory correlation centre. S. R. Detwiler : Experiments upon the segmentation of spinal nerves in salamander embryos. Reduction in number of ganglia following removal of somites and increase following insertion of an additional somite, support Lehmann's view that normal segmentation of spinal ganglia is determined by mesodermal metamerism. Harlow Shapley : A contribution to the study of galactic dimensions. Data from observations on isolated cluster type Cepheids in high latitudes indicates that these Cepheids outline the galactic system and may be so much as 30,000 light years from the galactic plane. Along the galactic plane the dimensions are probably greater, but direct measurement is rendered difficult by absorption. Peter M. Millman : The theoretical frequency distribution of photographic meteors. Donald H. Menzel : A simple derivation of the dissociation formula. The argument starts from Boltzmann's formula for the distribution of atoms in different energy states. Dean B. McLaughlin : A suggested mechanism of class *Be* stars. The spectra of these stars show wide emission lines of hydrogen divided by absorption lines, and cyclic changes of the relative intensities of the two components of each emission line occur. The stars are considered as having atmospheres so extensive and rarified that, to a first approximation, their atoms pursue independent orbits as satellites of the star, while the star itself is a temperature variable. E. B. Mains : Host specialisation of *Erysiphe graminis Tritici*. Two physiological forms of the powdery mildew of wheat have been found. Carl D. LaRue : Regeneration in mutilated seedlings. Cotyledons and hypocotyls of many different families rooted in nutrient solutions. The effect of light is different in different species and sometimes even for the cotyledon and hypocotyl of the same species. When the cotyledons were removed, the remaining plumules failed to develop. B. S. Hopkins and L. L. Quill : The use of non-aqueous solvents in the study of the rare earth group. Differences in solubility of rare earth salts in water are small and separation is therefore difficult. Various alcohols and ethers have been tried as solvents. Ethyl ether proved useful for the separation of neodymium and praseodymium nitrates. L. O. Brockway and Linus Pauling : The determination of the structures of the hexafluorides of sulphur, selenium and tellurium by the electron diffraction method. A beam of electrons of uniform velocity intersect at right angles a jet of the gas, and the electrons scattered at right angles to the original beam are recorded photographically. The results indicate octahedral models and the following interatomic distances : S—F, 1·58 ± 0·03 A. ; Se—F, 1·70 ± 0·03 A. ; Te—F, 1·84 ± 0·03 A. Wilder D. Bancroft and John E. Rutzler, Jr. : The agglomeration theory of sleep. Sleep of various forms is postulated as due to reversible coagulation of some of the proteins of the centres of consciousness ; it can be counteracted by the irritability of the sensory nerves. A peptising agent such as sodium rhodanate decreases this sensory irritability, but an overdose may affect the centres of consciousness and prevent sleep. Henry Eyring : The zero point energy and the separation of isotopes. A theoretical discussion based on the view that separation of isotopes in processes involving velocity of adsorption is a special case of the general influence of zero point energy on reaction velocity. John R. Bates : The reaction of hydrogen atoms with oxygen and the hydrogen chlorine reaction. Wilder D. Bancroft, Robert S. Gutsell and John E. Rutzler, Jr. : Reversible coagulation in living tissue (11). Chronic alcoholism has been benefited by treatment with sodium rhodanate (peptisation therapy). (*To be continued.*)

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Monday, May 22

Victoria Institute, at 4.30—(in the Central Hall, Westminster, S.W.1).—Prof. Albert Fleischmann: "The Doctrine of Organic Evolution in the Light of Modern Research".

Royal Geographical Society, at 5.30.—Squadron-Leader A. R. M. Rickards: "The Towns of Wadi du 'An and Hadhramaut" (*Geographical Film*).

Tuesday, May 23

London School of Hygiene and Tropical Medicine, at 3.15.—Dr. L. P. Lockhart: "Industrial Medicine as a Function of Public Health".*

Institute of Physics, at 5.15—(at the Royal Institution, 21, Albemarle Street, W.1).—H. Bradley: "Physics in the Boot and Shoe Industry".

Wednesday, May 24

University of Cambridge, at 5.—Sir Charles Sherrington: "Mechanism and the Brain" (Rede Lecture).

King's College, London, at 5.30.—J. L. Hammond: "The Growth of Common Enjoyment" (Hobhouse Memorial Lecture).*

Geological Society of London.—Discussion on "The Falling Water-Level in the Chalk under London", to be opened by H. Dewey.

Society of Chemical Industry (Food Group).—Annual General Meeting.

Thursday, May 25

Royal Society, at 4.30.—Dr. J. Chadwick: "The Neutron" (Bakerian Lecture).

London School of Hygiene and Tropical Medicine, at 5.—Dr. C. J. Thomas: "Physically Defective Children" (succeeding lecture on May 29).*

Courtauld Institute of Art, at 5.30.—P. Pelliot: "Recent Progress in Chinese Archæology".*

Chemical Society, at 5.30—(in the Meeting Hall of the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W.1).—Prof. H. E. Armstrong: "Chemistry at the Cross Roads" (Hugo Müller Lecture).*

Language in the Service of Science

SEEKERS after truth in Nature have always been regarded as disturbers of the peace and associates of the Evil One. It is not surprising, therefore, that throwing stones at men of science is a practice dating from very early times ; and it still continues, if in a somewhat different form. Since the powers of evil were let loose during the War, the earlier pebbles of theology have been largely replaced by the heavier stones of sociology, as expressed in a prize-epigram in the *Spectator* :

> Science finds out ingenious ways to kill
> Strong men, and keep alive the weak and ill—
> That these a sickly progeny may breed,
> Too poor to tax, too numerous to feed ;

and more recently science has been indicted as a primary cause of unemployment. There is, however, an older missile that critics, chiefly literary men, never cease to hurl : the man of science, they say, cannot make himself intelligible to ordinary people ; he abuses the English language, and has little or no literary feeling. Dr. Cyril Norwood, the headmaster of Harrow School, in a recent Friday evening discourse at the Royal Institution on "The Use of the English Language", allies himself with these critics, but his stones are so soft and so polished, and the material of them is so excellent, that, far from doing harm, they should do good, even if they only disturb the still waters of complacency.

In our rightful efforts to be natural, says Dr. Norwood, we easily become careless in the use of words and slip into colloquialisms, and even slang. Men of science labour under the further disadvantage, peculiar to themselves, that they have to use a highly technical vocabulary which, however intelligible it may be to students of the particular science, is frequently meaningless to ordinary men and women. "The use of technical terms may very easily lead writers to employ language as a set of symbols only, and they may lose all sense of living words." Technical language is a necessity, but its use is frequently overdone, and "men of science, even when writing for each other in scientific periodicals, would find that it would repay them to write as clearly and attractively as they can. They should regard technical and specially invented terms as a necessary evil, an instrument to be employed as sparingly as possible. For one of their main purposes must of necessity be the instruction of the general educated public who are not specialists in any sense, and certainly in the propagation of ideas one who can explain himself in language which ordinary men and women can understand has a great advantage over one who has not this power".

Scientific workers will, we believe, agree generally with Dr. Norwood's moderately-worded statements, but it will be news to many that instruction of the general public is one of their main purposes. Perhaps it should be; but there are few signs that it is so now. The investigator who is inclined to assume the rôle of populariser believes that if he does so his colleagues will accuse him of being superficial and inaccurate. There is, further, a doubt whether, as a rule, he is qualified to act in this capacity; for good popular exposition demands qualities that have little or no connexion with those which make for success in scientific research. The populariser of knowledge must be able to woo or conquer his reader's attention by favour or by force; he must steer a clear course between academic phraseology and the jargon called 'journalese'; he requires imagination to see things as ordinary people see them; and, last but not least, he needs a sense of style. Ability to write or to speak plainly and pleasantly is seldom associated in the same individual with ability to do original work—there are, of course, some notable exceptions—and it would be well if this fact were recognised by the popular Press, which has lately gone to extremes in 'animating' objective description by over-emphasising the personal element. We all realise the advantage of hearing or reading the words of a discoverer or author as they flow hot from his mouth or fountain-pen, provided he is a capable exponent; but we also realise how wise was Johnson to have a Boswell, and how fortunate was Darwin to have a Huxley and a Ray Lankester as disciples.

The question of technical vocabulary is admittedly difficult. Although most would agree that in certain sciences there are words and expressions that almost or quite defy translation into ordinary language, yet in the great majority of sciences, pure and applied, it is possible to do so, if with some loss of precision, by using suitable devices, such as periphrasis and analogy. These, however, should be employed with caution, because periphrasis is the fruitful mother of jargon, and analogy, when false or faulty, has ever been an *ignis fatuus*, leading to wrong turns in science, religion and philosophy, and so blocking their progress. Men of science and technologists nearly always write and speak as if they are addressing one another, although the slang they use, like common slang, is concise, and often remarkably expressive—to themselves. These remarks, however, apply with equal force to other professional workers: lawyers, economists, stockbrokers, architects, musicians and other professional men, all use their own special jargon, which few laymen can properly understand. Language has been compared with a living organism: it grows by assimilating more material than it discards, but its general structure remains intact. The simpler words that make the backbone of a natural language stand fast against the accidents of time and the desecrations of the profane; they are and will remain the best for common use.

On the point of clear and attractive writing, it will be admitted that scientific men are, as a rule, far too engrossed in their special subjects to give much heed to style or method of presentation. A clear, brisk, and accurate style is, however, within the compass of all; but it requires effort. "All beautiful work," said Ruskin, "is the easy result of long and painful practice"; and if the man of science will not learn the rules of good writing and concentrate on applying them, he can only blame himself if he fails to make himself understood, and if another succeeds in reaping where he has sown.

The word 'style' has several meanings: it may mean personal idiosyncrasy in expression; or mere ornament; more often, and perhaps more correctly, it means the power of expressing lucidly a sequence of ideas; but however it be defined, fundamentally it consists in choosing the right words and arranging them properly. "Style is connexion; art is putting things in their places," said the Master of Balliol (Jowett); and though we may hold his definition of art to be inadequate, we cannot dispute that, fundamentally, style *is* connexion: the connecting of words, of clauses in a sentence, of sentences in a paragraph, and of paragraphs in a composition; and all with the object of attaining clear and precise expression.

The secret of a lucid style, as Dr. Norwood reminds us, is to simplify: cut out the redundant words, first the nouns and then the adjectives; avoid where possible the use of abstract nouns and long words; and beware of circumlocutions! Observance of these simple rules will go far to produce a good style; but a few more may be added, for example, prefer the active form of the verb to the passive; avoid the use of too many noun-adjectives; and study the use of hyphens.

The noun-adjective is often clumsy or ambiguous, and the rules or conventions for the proper use of hyphens (see Tract No. VI of the Society for Pure English) are honoured far more in the breach than in the observance in modern scientific literature.

The other main element in a good style is precision. "The chief aim in style," said Flaubert, "ought to be absolute precision. There is only one noun that can express your idea, only one verb that can set that idea in motion, and only one adjective that is the proper epithet for that noun." The chief obstacles to precise statement are want of clear thinking; bad choice of words; using too many abstract nouns, preposition-verbs, and circumlocutions; and faulty arrangement. Metaphors and analogies are useful in popular description, but find little place in rigidly scientific prose, as they often lack precision. Conciseness, first cousin to clarity, does not always make for precision, at least not for Flaubert's "absolute precision". It is possible to be too concise (as readers of many modern abstracts are aware) and to introduce ambiguity by cramming a maximum of meaning into a minimum of words. On the other hand, what is more tedious than reading a treatise by an author who leaves nothing to his reader's imagination, and disgorges the whole contents of his mind in sentences replete with qualifications and elaborations? The artist, it has been said, is known rather by what he omits. Can we not all emulate the artist in this respect?

Other hall-marks of a good style are variety and sobriety. Although often guilty of monotony, scientific writers of to-day can seldom be accused of want of sobriety; they err rather in the opposite direction, except when they make two or more words do the work of one. The populariser must, of course, be allowed some licence; he has to fix and maintain the attention of his audience; and if at times he tries to imitate authors like Shaw and Chesterton by immoderate use of hyperbole, paradox, parody, and alliteration, he may be forgiven on the ground that the end justifies the means. Nevertheless, the elements of style are essentially the same for popular scientific, purely scientific, and ordinary literary description. If the writer of science is to be as successful as the literary man in his appeal to the educated public, he must observe the 'rules of the game', and furthermore, he must cultivate that priceless possession of the true artist and the real man of science, the passion to excel, which is at the root of all the best work that is done in the world.

Metals and Civilisation

Man and Metals: a History of Mining in relation to the Development of Civilisation. By Dr. T. A. Rickard. Vol. 1. Pp. xiii+506. Vol. 2. Pp. v+507–1068. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1932.) 50*s*. net.

BUCKLE devoted six volumes to an introduction to the history of civilisation. Dr. T. A. Rickard gives us two bulky volumes on a single aspect of this subject, an aspect somewhat neglected by Mr. H. G. Wells, namely, the relation of mining and the use of metals to the development of civilisation.

It may reasonably be said that no man living is better qualified to write on this subject than Dr. Rickard. He was trained at the Royal School of Mines, London. Since his student days he has spent nearly fifty years as a mining engineer, mine manager and consultant in various parts of the world, but chiefly in the United States. He has been editor successively of three leading mining journals. He is also the author of several textbooks on mining subjects.

In his introductory chapters, Dr. Rickard shows how man emerged from savagery by the aid of tools, first of wood and stone, then of metal. In the masterly review of the history of mining which follows these introductory chapters, the author shows how the search for metals has aided the spread of civilisation in ancient times, in the Middle Ages, and in our own era. Also how the use of metals for money, credit, machinery, transport, communication and war has been a fundamental factor in the development of our present world-wide civilisation.

The author also dwells on the perversity of mankind through which a blessing is often converted into a curse. In the earliest times "the sword was made before the ploughshare"; in the immediate future "shall we mend our ways or go with the Gadarene swine down the steep slope of perdition?" "The history of mining, like all other history, thunders a warning."

Dr. Rickard is a philosopher as well as a historian and an engineer; he is also a careful student. The dedication of his book "To the Librarians" indicates his appreciation of the work of others. The lengthy lists of references at the end of each chapter are evidence of the care with which he has studied his subject. Nevertheless, the treatment in places seems to follow the preconceived methods of some mining geologists rather than the cautious following of the reef characteristic of the old-fashioned mining engineer. Dr. Rickard condemns rather thoroughly the legend of King Solomon's mines in Rhodesia and prefers the later theory that they are of recent Bantu origin. He offers no explanation of the destination of the very large amount of gold apparently taken from these workings, or of the workmanship of the gold ornaments, or of the finely made crucibles apparently used for assaying. These crucibles were turned on a wheel, not Bantu work, and may be found also around the ancient workings of Rouiberg and Blaubank in the Transvaal. These crucibles in *both* countries are characterised by a herring-bone pattern round the rims. The objections to South Africa not being regarded as a great centre for bronze and copper production are similar. The Middle Ages had no use for the million tons of copper estimated by Dr. P. A. Wagner to have been produced: nor is there any record of the thousands of tons of tin produced being shipped to Europe in the Middle Ages. In one district alone there are the remains of forty-six furnaces and enormous quantities of slag. The occurrence of nickel in ancient bronzes does not seem explicable from the limited Hungarian and Asiatic sources alone, but, as Dr. Rickard remarks, the chemical analysis of metallic relics has been sadly neglected. Many a "Green-stained piece of old metal" has been assumed to be bronze when often it was copper. He also, on geological grounds, denounces as fable the stories of the rapid submergence of Leonesse in November 1099.

Again, Dr. Rickard bases some important conclusions on the statement that the pre-Roman Britons only possessed tools of wood and deers-horn. From "across the pond" we must remind him that Cæsar's world-victorious army was defeated again and again and finally driven from Britain in 55 B.C.—surely not with tools of wood and deershorn! The Romans did not finally conquer Britain for another hundred years although attempts were made.

In these days of specialised study, it is often easy to find fault with any book which deals with a very wide subject. Dr. Rickard's main conclusion is well and truly established; he has shown convincingly the intimate relation between the history of mining and the history of man's development from savagery, through barbarism to civilisation. B. W. H.

A Photogrammetric Survey in the Pamir

Wissenschaftliche Ergebnisse der Alai-Pamir Expedition 1928. Im Auftrage der Notgemeinschaft der Deutschen Wissenschaft. Herausgegeben von Dr. H. v. Ficker und Dr. W. R. Rickmers. Teil 1: *Geodätische, Topographische und Glaziologische Ergebnisse.* Von Dr. Richard Finsterwalder. Band 1: *Geodätischer und glaziologischer Teil.* Pp. x + 218 + 23 plates. Band 2: *Kartenbeilagen.* 12 maps. Teil 2: *Geologische Untersuchungen im nordwestlichen Pamir-Gebiet und mittleren Transalai.* Von Dr. Ludwig Nöth. Band 1: *Stratigraphie (ausschliesslich Quartär), Tektonik.* Pp. viii + 130 + 3 maps. Band 2: *Quartäre Ablagerungen, Morphologie.* Pp. v + 131–211 + 24 plates. Teil 3: *Beiträge zur Faunistik des Pamir-Gebietes.* Von Dr. W. F. Reinig. Band 1: *Ökologie und Tiergeographie.* Pp. viii + 195. Band 2: *Systematischer Teil.* Pp. iv + 196–312 + 6 plates. (Berlin: Dietrich Reimer (Ernest Vöhsen) A.-G., 1932.) 6 vols., 175 gold marks.

THE Alai-Pamir expedition was a joint undertaking of the Notgemeinschaft der Deutschen Wissenschaft and the Academy of Sciences of the U.S.S.R., and its object was to explore the almost unknown north-western part of the Pamir. The sheet of the general map which accompanies these volumes extends from 72° E. to 73° 45′ E. and from 38° 30′ N. to 39° 40′ N., and most of this area was surveyed in greater or less detail. The actual survey reaches from the Kisil-su on the north to the southern border of the sheet, and from the Garmo Peak on the west to the Pamirski Post road on the east, stretching beyond that road in the Transalai and in the neighbourhood of Lake Karakul. The area covered by the survey is about 15,000 square kilometres.

The expedition entered this area at the north-east corner on June 27 and left at the north-west corner on Oct. 16, and the topographical map is a truly remarkable result for less than four months' work in so difficult a region. That so much was accomplished is due to the foresight with which the expedition was planned and to the fact that the survey was made by terrestrial photogrammetric methods and was plotted with the stereo-autograph after the return to Europe. No previous expedition in unknown country has relied so entirely upon these methods, and the very practical account given by Dr. Finsterwalder should be valuable to workers in other areas. He deals not only with the observations in the field but also with the subsequent preparation of the map, by the field observers themselves, with the help of the stereo-autograph. The chief instrument used in taking the photographs was the light phototheodolite of Zeiss; but where the difficulties of access were too great, a still lighter photogrammeter, without theodolite and using smaller plates, was employed for supplementary observations. Other instruments were used for triangulation and for field astronomy, and the astronomical position of several points was accurately fixed by Belajeff, one of the Russian coadjutors, with a more complete astronomical equipment. Two stations of the Russian Pamir Triangulation were found and thus the survey was linked with previous work. Certain discrepancies between astronomical and geodetic positions indicate deflections of the plumb-line which deserve closer investigation.

The area examined varies greatly in character. Towards the south-east it is a dry plateau where rock-waste accumulates and the hills are low and tame. Towards the west and south-west the rainfall increases, snow gathers on the higher ground, and large glaciers flow out from extensive snowfields. The valleys here are deeply cut and the hills are rugged, especially near the Garmo Peak. On the north is the high chain of the Transalai, with smaller snowfields and glaciers, and beyond this lie the steppes of the Alai Valley, through which the Kisil-su flows from east to west.

The most interesting part of the region, from the morphological point of view, is the glaciated area of the west and south-west. The topographers spent some eight weeks here, the survey was made in considerable detail, and the rate of movement of two of the greatest glaciers was determined. The method by which this rate was measured shows some of the advantages of photogrammetry. From the ends of a measured base upon the bank photographs are taken with the photo-theodolite, looking across the glacier. After the lapse of a few days one at least of these photographs is repeated. With the stereo-autograph there is then no difficulty in determining with considerable precision the distance which any stone or other well-defined mark upon the glacier has moved during the interval. In sunny weather this interval must not be too long or some of the movement of a stone may be due to melting of the ice. One of the glaciers of which the rate was determined was the Fedchenko Glacier, the most remarkable of all. It flows from south to north, at right angles to the general trend of most of the main valleys. Its length is about seventy-four kilometres and Finsterwalder thinks that it is probably the longest glacier on the earth outside the polar regions.

A geologist can do nothing where the rocks are covered with snow, and accordingly Dr. Nöth devoted his attention chiefly to the north and east of the region. With the help of the observations of his colleagues he has produced a geological map of the whole area, but he is fully aware that such a map can be no more than an imperfect sketch. It will, however, be useful both to the reader and to any subsequent worker in the region.

By far the greater part of the north-western Pamir consists of Palæozoic and older rocks, with large intrusive masses. Lower Carboniferous beds have been definitely recognised, Middle Devonian and Permian beds with less certainty. The folding of these rocks was completed in the Permian period and the mass was raised above the sea. The Mesozoic era was a quiet time during which a surface of low relief was produced by erosion, the hills which rose above the general level being worn down, while in depressions below that level Mesozoic sediments were locally deposited. The Transalai range, on the northern border of these ancient rocks, is geologically distinct. Its northern slope consists of Cretaceous and Tertiary beds which have been strongly folded by a northward movement of the Pamir mass. This folding was completed in Miocene times and since then there has been no great change of form in any part of the region; but the valleys upon the western border have been deepened by ice and river erosion, while in the dry interior the rock-waste produced by weathering remains. Two glacial periods can be recognised, during the first of which the glaciated area was considerably more extensive than during the second.

Dr. Reinig, the zoologist of the German party, began to collect in the Fergana basin, before the expedition had reached its chief objective. He left the main party near Lake Karakul and travelled through the south part of the Pamir as far as Langar, near the border of Afghanistan. Accordingly, he deals with a much wider area than his colleagues. In the circumstances it was impossible to preserve or transport soft-bodied animals. Therefore he collected chiefly insects, paying special attention to bees and Tenebrionidæ, which, on account of their variability, might be expected to yield the most valuable results. He gives a useful general account of the orography, climatology and vegetation of the whole region; but perhaps his most interesting chapter is that upon the origin of the Pamir fauna. Owing to its cold and dry climate the fauna of the High Pamir is much poorer, both in species and in individuals, than that of the milder and moister western valleys; but there are differences which cannot be due entirely to climate. During the first glacial period much of the Pamir was covered by ice, and animal life must have been greatly reduced. Most of the present fauna has entered the area since the ice retreated, and Dr. Reinig shows that there has been immigration both from the west and from the east. Another chapter, of special interest to zoologists, deals with variation in the Hymenoptera and Tenebrionidæ.

The whole work is beautifully produced and the volumes are very convenient to handle and read. The paper is thick and strong but very light, and the print is clear. The numerous photographic views and panoramas are well reproduced and the maps and sections leave nothing further to be desired. Besides the general topographic map on the scale of 1 : 200,000 and the geological map upon the same scale, there is another with the contours in blue and the trigonometrical nets in red, and a transparent sheet showing the photogrammetric lines. There are also special maps of the greater glaciers on a larger scale, sections of two of them showing the rate of movement, and a sheet of geological sections. PHILIP LAKE.

The Play of Thought in Progress

Adventures of Ideas. By Prof. Alfred North Whitehead. Pp. xii + 392. (Cambridge: At the University Press, 1933.) 12*s.* 6*d.* net.

THIS is a book so rich in thought and covering so many fields of human experience that it is quite impossible to summarise or render an adequate account of it within the limits of a review. It is emphatically a book to be bought, read, re-read, and pondered. Not everyone will agree with the author's views, which are the expression of a highly individual philosophy, a particular attitude towards the problems of existence, but no one can read the book without receiving help and stimulus from the wisdom that permeates it and flashes into brilliance in many pregnant phrases.

The book is complementary to "Science and the Modern World" and "Process and Reality", but is complete in itself, and can be read without previous acquaintance with Whitehead's philosophy. There are four sections. The first deals with the influence exerted by Platonic, Roman, and Christian ideas upon the development of Western civilisation.

In a few vivid chapters, Whitehead traces the growth of the humanitarian ideas which originated first as the intuitions of genius, and slowly made their way in the world, as the world ripened to receive them. Thus "at the close of the Dark Ages Europe started upon its second effort after civilization with three main advantages: its Christian ethics: its instinct for legal organization transcending local boundaries, derived from the Church and the reminiscence of the Empire: and thirdly its wider inheritance of antecedent thought, gradually disclosing itself as Hebrew, Greek, and Roman literatures. The total effect was the increased sense of the dignity of man, as man. There has been a growth, slow and wavering, of respect for the preciousness of human life. This is the humanitarian spirit, gradually emerging in the slow sunrise of a thousand years" (p. 105). This is what Whitehead means by the adventure of ideas in the history of the human race—their influence in promoting "the slow drift of mankind towards civilization".

There is, too, in all great thought an element of adventurousness—fresh ideas represent something novel, untested, unsafe: they are a leap in the dark. It is of the essence of life itself that it is a striving after expansion and novelty. It is "an offensive, directed against the repetitious mechanism of the Universe. . . . Life can only be understood as an aim at that perfection which the conditions of its environment allow. But the aim is always beyond the attained fact" (p. 102).

A civilisation which has become static, which rests content with accepted ideas and customs, which puts safety first and refuses the adventure of ideas, is a civilisation about to decay. It can be rescued and transformed only by the influence of fresh ideas, new ends to pursue. "The foundation of all understanding of sociological theory—that is to say, of all understanding of human life—is that no static maintenance of perfection is possible. This axiom is rooted in the nature of things. Advance or Decadence are the only choices offered to mankind. The pure conservative is fighting against the essence of the Universe'

(p. 353). Our present civilisation has reached a period of stagnation and is doomed to slow decline unless some fresh and revivifying creative ideal emerges. Let us hope, with Whitehead, that "our present epoch is to be viewed as a period of change to a new direction of civilization".

In the second section of the book, Whitehead deals in similar fashion with the influence of scientific ideas upon European culture. Here again we meet with a rich tangle of thought to which a reviewer can do but poor justice. There is a valuable discussion of the main doctrines concerning the laws of Nature, of which Whitehead distinguishes four—the doctrine of law as immanent, the doctrine of law as imposed, the doctrine of law as mere description, and the more modern doctrine of law as conventional interpretation. The influence of these varied conceptions of natural law upon scientific cosmologies is traced out historically.

Linked with this general discussion is a brilliant treatment of the interplay of "speculation" and "scholarship"—another facet of the adventure of ideas. Their contrast is exemplified by the Greeks of the classic period and the later Alexandrians. "The note of Hellenism is delight, speculation, discoursive literature: the note of Hellenistic Alexandria is concentration, thoroughness, investigation of the special types of order appertaining to special topics". Both are necessary for the advance of knowledge and understanding, but their proper balance is rarely achieved.

Nowadays, according to Whitehead, the balance has tipped too far in the direction of "scholarship". "Modern scholarship and modern science reproduce the same limitations as dominated the bygone Hellenistic epoch, and the bygone Scholastic epoch. They canalize thought and observation within predetermined limits, based upon inadequate metaphysical assumptions dogmatically assumed. The modern assumptions differ from older assumptions, not wholly for the better. They exclude from rationalistic thought more of the final values of existence. The intimate timidity of professionalized scholarship circumscribes reason by reducing its topics to triviality, for example to bare sensa and to tautologies. It then frees itself from criticism by dogmatically handing over the remainder of experience to an animal faith or a religious mysticism, incapable of rationalization" (p. 151). New directions of thought are required, and they will come through flashes of intuition, commencing as "sheer ventures of rash speculation", which will be tested, criticised, exemplified, extended, by the patient work of scholarship and research.

The third part of the book is headed "Philosophical" and it contains a condensed account of Whitehead's own system of philosophy. It is extremely hard reading, and is likely to be refractory to any but the professional metaphysician. For this reason, no attempt will be made here to expound it.

The last section deals with truth, beauty, art, adventure, peace, as qualities which should characterise a civilised society. The last two chapters are particularly fine; in them Whitehead frees his thought from its often difficult and obscure expression and writes vividly and clearly. It is in these chapters that one can best grasp the purport of the book, and share the vision of reality which our great poet-philosopher offers us.

I conclude with one further quotation, which gives some notion of what Whitehead means by "Peace". "The vigour of civilized societies", he writes, "is preserved by the widespread sense that high aims are worth while. Vigorous societies harbour a certain extravagance of objectives, so that men wander beyond the safe provision of personal gratifications. All strong interests easily become impersonal, the love of a good job well done. There is a sense of harmony about such an accomplishment, the Peace brought by something worth while" (p. 371).

E. S. R.

Short Reviews

Strahlenoptik. Von Dr. M. Herzberger. (Die Grundlehren der mathematischen Wissenschaften in Einzeldarstellungen mit besonderer Berücksichtigung der Anwendungsgebiete, herausgegeben von R. Courant, Band 35.) Pp. xiii + 196. (Berlin: Julius Springer, 1931.) 19.40 gold marks.

THIS volume, which is not a textbook, embodies recent work by the author and other workers, carrying this further in an attempt to give a unified exposition of erstwhile geometrical optics, not by the usual devious routes but rather by consistent application of the original method of Hamilton. The author goes far towards achieving this, although finding himself compelled to resort to conventional methods when considering the limitation of rays. The subject, still in essence geometrical optics, gains considerably in perspicuity by reason of the inherent advantages of the method and the conciseness of Herzberger's treatment. The author's additions to the terminology are not such obvious gains.

As befits one of a well-known series of mathematical monographs, the treatment most appropriate to the subject has been employed. This assumes substantial acquaintance with the properties of matrices and the vector method, such as rather to limit the appeal of the work among average students.

The book, consisting of eight parts, may be considered in two divisions. In Parts 1–4, after a brief general consideration of systems in anisotropic media, the basis is laid for the subsequent treatment, ray-tracing formulæ being given incidentally. The chapter on Gaussian optics includes consideration of the general case with references to Gullstrand.

In Parts 5–8, devoted to the theory of aberrations, a system of first order aberrations is worked out without applications, and generalities are given for finite aperture and field. The author follows T. Smith closely, the last part being confined entirely to work by this writer.

Adequate bibliographical reference is for the most part given, although one misses mention of certain names which suggest themselves in places (for example, Rayleigh, Schwarzschild).

Handbuch der physikalischen und technischen Mechanik. Herausgegeben von Prof. Dr. F. Auerbach und Prof. Dr. W. Hort. Band 3: *Statik und Dynamik elastischer Körper nebst Anwendungsgebieten, zum Gebrauch für Ingenieure, Physiker und Mathematiker.* Pp. ix + 468. 32 gold marks. Band 4, Hälfte 1: *Statik und Dynamik elastischer Körper nebst Anwendungsgebieten, zum Gebrauch für Ingenieure, Physiker und Mathematiker.* Lief. 1. Pp. vi + 198. 16 gold marks. Lief. 2. Pp. xiv + 199–636. 72 gold marks. Band 4, Hälfte 2: *Technische Physik der festen Körper, zum Gebrauch für Ingenieure, Physiker und Mathematiker.* Pp. xiii + 614. 75 gold marks. (Leipzig: Johann Ambrosius Barth, 1927–1931.)

THIS monumental handbook in seven volumes now nears completion, the only outstanding parts to be published being the conclusion of vol. 5 (on the mechanics of fluids) and the complete index for the whole work. Of the volumes here noticed, the first (vol. 3), besides covering familiar ground in elasticity, includes an article on earthquakes and seismic waves, by Gutenberg. Vol. 4 ranges over a wide field of technical elasticity and the properties of matter, and summarises much work that is not otherwise easily accessible in collected form. Among the articles may be mentioned several on crystal structure (including one on polycrystals and their investigation by X-rays), two on the growth- and deformation-texture of organic substances and of metals, and one on workshop testing of materials. A regrettable feature of the publication is the very high price (particularly in sterling) of the last published, vol. 4.

Methods of Social Study. By Sidney and Beatrice Webb. Pp. vii + 263. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1932.) 8*s*. 6*d*. net.

THIS excellent work gives the prolegomena to an applied science of society. The authors think that sociology has reached the stage occupied by the physical sciences a century ago; and that scientific method can be strictly applied to help the theoretical and practical progress of sociology. Such developments as the adoption of an official audit in public administration, the recruitment of civil servants and the organisation of trade unions, are not merely the outcome of blind forces hazily understood by the trial and error method, but the result of hypotheses actually arrived at by social workers and philanthropists working along the lines of scientific method. The authors of this work then discuss questions relating to the mental equipment of the social investigator, to the study and compiling of social facts and to the use of statistics. The great difference between social and physical sciences is given by their object: "Treasure your exceptions" should be the motto of the first; "scrap your exceptions" seems to be the physicist's point of view. Hence the social problem is not to find out how to get men and women to fit into society, but how to make a society into which will fit the men and women with all their differences and peculiarities of character, health and occupation. T. G.

Zoologie der Madagascar. Par G. Grandidier et G. Petit. Pp. 258 + 48 plates. (Paris: Société d'Éditions Géographiques, Maritimes et Coloniales, 1932.)

THIS is the first of a series of useful semi-popular volumes dealing with the land of the lemurs. It is admirably illustrated and fulfils its purpose well. One of the authors clearly has an intimate personal knowledge of the mammals, the account of which occupies nearly half the work and is illustrated by 27 plates. The invertebrates are treated very briefly, for as yet they are little known. The bibliography is particularly valuable. The French know how to write such books; they select the form in which they might lecture, bringing in all necessary scientific facts, but no others, in an attractive manner.

Elementary Physics: for Medical, First Year University Science Students and General Use in Schools. By G. Stead. Fourth edition. Pp. xiv + 457. (London: J. and A. Churchill, 1933.) 10*s*. 6*d*.

IN this, the fourth edition of the book, very few changes have been made but some additional matter has been introduced, notably in the sections on X-rays and radioactivity. Both of these, although brief, appear to be somewhat too advanced for so elementary a work. The book should be of use to medical students, for whose benefit the mathematical work has been reduced to a minimum.

Structure of Alloys*

By PROF. W. L. BRAGG, O.B.E., F.R.S.

WHEN one metal is alloyed with another, in a series of varying relative proportions, generally several new alloy structures (phases) appear which are different from each other and from the structures of either pure metal. In the usual type of diagram, the composition of the alloy is represented along a horizontal scale starting with the pure metal *A* on the left side and ending with the pure metal *B* on the right side: temperatures are plotted vertically. In a typical case, the addition of small quantities of the metal *B* to the metal *A* does not alter its characteristic structure, the atoms remaining in the same relative arrangement. Atoms of *B* replace a corresponding number of atoms of *A* in an apparently random manner, and the only observable change is a uniform contraction or expansion of the *A* lattice. There is thus a more or less extended single phase region on the left of the diagram. As the proportion of *B* is increased, a limit is reached at which the *A* structure can no longer absorb *B* atoms in this way, and beyond this point a new phase appears. The new phase, which is richer in the *B* constituent, has a different atomic arrangement, as has been confirmed by X-ray analysis. Throughout a certain range of composition the two phases co-exist and each is constant in composition, the amount of the first phase decreasing and of the second phase increasing in passing through the two-phase region from left to right. The first phase finally disappears, and a new region of single phase is entered, to be succeeded by two-phase regions and single phase regions alternately. The last single phase region on the right hand side includes as a limiting case the pure metal *B*.

Such phase diagrams have been worked out for many alloys by metallurgical methods. The boundaries between single phase and two-phase regions are determined by examining polished and etched surfaces under the microscope, and thermal and electrical measurements aid in outlining the diagram. The single phase regions are bounded on each side by lines of which the departure from the vertical shows that the extent of the phase is, to some extent, dependent upon temperature. The liquidus and solidus boundaries above each phase region show at what temperatures solidification from the melt begins and ends.

In recent years, X-ray methods have played an important part in the construction of phase diagrams, the 'powder method' being particularly suitable for this purpose. Westgren's name will always be associated with this field of inquiry, in which he was a pioneer. Several methods differing in their experimental detail have been used. In one method the alloy in the form of a fine powder is placed in a Debye-Scherrer camera, and irradiated with monochromatic X-rays of suitable wave-length. The diffracted beams form a pattern of lines upon a strip of photographic film, which is in the form of a cylinder with the powder at its axis. The pattern is characteristic of the alloy structure, and if not too complex, the structure can be completely analysed by studying the pattern it produces. In a single phase region the character of this pattern remains the same throughout the range of composition, the only change being a shift in the positions of the lines due to the expansion or contraction of the lattice. When the boundary of the single phase region is passed and the two-phase region is entered, the photographs show the pattern of both constituent phases superimposed. The lines of one become fainter, and of the other stronger, as the region is traversed. Since in this region each phase is constant in composition, the lines, though altering in intensity, do not shift their positions. If the lattice dimensions of a phase as determined by the powder photograph are plotted against composition, a sloping line is obtained in the single phase region and a horizontal line in the two-phase region. The composition at which the two lines intersect is a highly accurate index of the position of the phase boundary.

X-RAY TECHNIQUE

The wave-length of the radiation used in making the photographs must be adapted to the alloy which is being examined. It must not be absorbed too heavily by the alloy powder, both because the diffracted lines are then weak, and because the absorption implies a re-scattering of radiation in all directions with consequent darkening of the background. For example, cobalt, iron and chromium $K\alpha$ radiations are excellent for examining iron alloys, since they are of lower frequency than the iron 'absorption edge' and hence are little absorbed. A cobalt radiation gives a large absorption of cobalt $K\beta$ rays in the specimen if these waves have not previously been filtered out. Copper radiation is extremely inefficient owing to the very large absorption, which produces a blackened film on which scarcely any lines are discernible.

It is possible to obtain powder photographs which at the same time give the pattern of lines throughout the complete circle, and enable the lattice dimensions to be worked out with high accuracy. The latter are most useful indices in elaborating the phase diagram. A recent design of camera by Bradley, combined with an ingenious method of evaluating the results, enables spacings to be compared with an accuracy approaching 1/50,000 when the crystalline material is suitable, while at the same time the camera is of the ordinary circular type utilising short exposures and including the complete pattern. All 'precision methods' of measuring spacing depend upon the useful feature that rays diffracted backwards through nearly 180° enable a very accurate comparison of spacing with wave-length to be made. The particular feature of the method referred to above is the way in which errors due to incorrect placing of the specimen, absorption in the specimen, film shrinkage, and uncertainty as to camera-radius, are automatically eliminated.

---

* Friday evening discourse delivered at the Royal Institution on March 17.

Powder cameras must be calibrated by taking in each camera a photograph of a crystal with known spacings. Quartz is very suitable for this purpose. It is constant in composition, has a small temperature coefficient, and gives a large number of very clear lines. The quartz photograph may become as important in X-ray work as the comparison iron spectrum in spectroscopy.

NATURE OF A 'PHASE'

The determination of phase boundaries by X-rays is merely the application of a new method to a problem already dealt with by well-established metallurgical technique. The particular contribution of X-ray analysis is its determination of the atomic arrangement in the alloy. It is found that each phase has a characteristic geometrical pattern of atomic positions. This is in accord with the findings of analysis in other crystalline bodies such as inorganic and organic compounds, but there is a new feature in alloy structures which is peculiar to them. The phase is an absolutely definite arrangement of 'sites' for atoms, if one may put it in that way, but in many cases the way in which the atoms are distributed amongst these sites turns out to be of secondary importance, and may vary widely. Such a feature is foreign to the typical inorganic or organic compound, where the atoms of various kinds have each their appointed positions.

An example of this peculiar feature is given by the structures of two closely related alloys the compositions of which approach the ideal formulæ Cu_5Zn_8 and Cu_5Cd_8. These alloys, which appear as phases in the copper-zinc and copper-cadmium systems, are obviously similar in nature. They are hard and brittle with a characteristic fracture and sheen. X-ray analysis by Bradley has determined their complex structure, in which there are 52 atoms in the unit cube, the 'γ structure'. From the similarity in atomic ratio and the correspondence in chemical properties of zinc and cadmium, it would be expected that the arrangement of zinc atoms in one and of cadmium atoms in the other would precisely correspond. The sites for atoms in the two alloys are indeed almost identical, but Bradley has been able to show that the distribution of zinc atoms amongst these sites in the one alloy is entirely different from the arrangement of cadmium atoms in the other. Clearly the peculiar complex γ structure is determined by something apart from the distribution of the atoms; the latter is a secondary feature influenced by the relative sizes of zinc and cadmium atoms.

We find similar phases, or arrangements of atomic sites, in different alloys. For example, the alloys of copper, silver, gold with metals of the *B* subgroups such as zinc, cadmium, aluminium, gallium, tin form an α face-centred cubic phase like that of copper, silver, gold themselves, a body-centred β phase, and a complex γ phase with 52 atoms in the unit cell. All γ phases have similar physical characteristics such as their extreme hardness. Since the geometrical arrangement of atomic sites in each phase appears to be quite definite, while at the same time independent of the atomic distribution, by what is it determined?

HUME-ROTHERY'S LAW

The answer to this question is provided by a brilliant hypothesis which we owe to Hume Rothery, the truth of which has now been verified by a large number of examples. Hume-Rothery's law states that each phase appears when the ratio of valency electrons to atoms has a value characteristic of that phase. For example, the β phase, which is body-centred cubic, is found when there are three valency electrons to every two atoms, examples being the alloys CuZn, Cu_3Al, Cu_5Sn. Assigning one valency electron to copper, two valency electrons to zinc, three to aluminium, and four to tin, it will be seen that in the first of these compounds there are three electrons to two atoms, in the second six electrons to four atoms, and in the third nine electrons to six atoms. An even more striking example is found amongst the γ structures to which reference has already been made. Here the electron-atom ratio is 21 : 13, examples being Cu_5Zn_8, Cu_9Al_4, $Cu_{31}Sn_8$. A hexagonal, close-packed ε structure which appears in many of the alloy systems has a ratio 7 : 4, as evidenced by $CuZn_3$, Cu_3Sn, $AgZn_3$, Ag_5Al_3, $AuCd_3$. A very large number of alloys obeying this law is now known, and it will no doubt be added to as other systems are examined.

There are exceptions to the rule. It must further be borne in mind that an alloy phase is not definite in composition but extends over a range in the phase diagram which may be broad or narrow. The composition which gives one of the above ideal electron-atom ratios may be towards one side of the single phase region, or even just outside it. It is justifiable to say, however, that the electron-atom ratio is a main factor in determining the arrangement of atomic sites in the phase. The range of the phase is modified by other factors, which make it broad or narrow and displace it one way or the other, but they are of secondary importance. Starting with copper, silver, or gold and alloying them with other metals, we run through a similar series of phases. The higher the valency of the second metal, the smaller is the amount of it which has to be added in order to produce each new phase. Quantitatively this may be expressed by saying that its contribution is to be reckoned in terms of added valency electrons, according to Hume-Rothery's law.

It is an interesting feature that the metals of the triads iron, cobalt, nickel; ruthenium, rhodium, palladium; *osmium, iridium, platinum*; form similar phases of the β and γ types. In these alloys the valency *zero* must be assigned to the transition metals; for example,

3 : 2 phase FeAl, CoAl, NiAl
21 : 13 phase Fe_5Zn_{21}, Co_5Zn_{21}, Ni_5Zn_{21}, Rh_5Zn_{21}, Pt_5Zn_{21}.

To sum up, the arrangement of atomic sites in an alloy phase appears to be due not to the interaction between the metals of one kind and those of another kind, but to the interaction between all the metal atoms on one hand, and the common electronic structure, to which they join in contributing their valency electrons, on the other hand. The metal atoms can be shuffled about between the phase-sites without a profound alteration of the nature of the phase, as if the structure were almost indifferent to the nature of the atoms in the various sites so long as they provided the quota of valency electrons. It has been shown by Bradley, for example, that ternary alloys and presumably alloys of any complexity assume the γ phase if the total electron-atom ratio is 21 : 13.

SEGREGATION OF ATOMS INTO PHASE-SITES

Two aspects of the problem of alloy structure may thus be distinguished. The first concerns the geometrical arrangement of the sites for atoms, characteristic of each type of phase. Its elucidation must be sought for in the electron-atom interaction as part of the problem of metallic structure in general. The second concerns the way in which the atoms distribute themselves amongst these sites. It has been known for some time that this distribution may vary in a given phase. On one hand, atoms of each kind may segregate into certain positions in a symmetrical way, so as to build a crystal structure of definite pattern like those found in inorganic and organic compounds. In some of the γ alloys, for example, similar atoms occupy certain sets of the sites which are related by the crystal symmetry, and the other atoms occupy the remainder.

Alternatively, we may find the formation of a *super-lattice*. In a simple β structure of the body-centred cubic type, for example, there are two atomic positions in each unit cubic cell, at corners and centres, which are crystallographically identical. In such structures as CuZn, or FeAl, one atom occupies the corners and the other the centres. In β alloys of more complex composition, however, the unit of pattern repeats in a larger distance, so that it is necessary to stack several cubes together and select symmetrically certain positions from the large unit for one of the atoms, in order to represent the unit of pattern. An X-ray photograph of such an alloy shows as a primary feature the lines due to the body-centred cubic arrangement characteristic of all β phases. In addition, subsidiary lines due to the super-lattice appear, which indicate that the unit of pattern is upon a larger scale. The segregation of the atoms into preferred positions may be followed by studying these lines.

As opposed to the formation of a super-lattice or of a regular crystalline segregation, we find in other cases that the X-ray diagram indicates merely the arrangement of the atomic sites, as if the atoms were arranged in an absolutely random manner amongst these sites. Such a random arrangement would affect the X-ray diffraction pattern as if each site were occupied by an identical unit of mean composition. Many examples might be quoted, a very striking one being given by Westgren. The alloy Cu_5Si has a complex structure in which there are twenty atoms in the unit cube. This β′ structure is assumed instead of the simple β structure by certain alloys with a 3 : 2 electron ratio, and is similar to one form of the element manganese, the β-manganese structure. An X-ray photograph of Cu_5Si gives lines identical in arrangement and relation in intensity with those of β-manganese, in which, of course, all atoms have the same scattering power, so that the scattering by each atomic site must be that of a mean effective atom. Further, it may be noted that the six atoms of Cu_5Si cannot be distributed in any regular way between twenty atomic positions, since 6 is not a factor of 20. Structures which give such an effect are said to be structures of *random replacement*.

The transition between the two extremes of regular and random replacement may be observed in one and the same alloy. Alloys at high temperatures or which have been rapidly quenched from high temperatures show random arrangement, whereas alloys subjected to prolonged annealing have a regular or super-lattice structure. The potential energy of the symmetrical structure must be less than that of the disordered structure, and hence it is the stable structure at low temperatures. At high temperatures, however, the thermal movements are causing the atoms constantly to change places, a disordered arrangement having a higher entropy than an ordered arrangement.

The study of these changes in arrangement is of great interest and importance, because they affect the physical properties of the alloy. It is to be emphasised that we are not concerned here with a phase change, since the phase remains the same throughout. We are dealing with continuous changes from order to disorder within the same phase structure.

The segregation of atoms into regular positions was surmised by Tammann in 1919 as an explanation of the changes in resistance of annealed alloys. One of the most fully examined cases is that of the gold copper alloy AuCu studied by Johannson and Linde. In this case we are dealing not only with regular and irregular distribution of atoms, but also with an alteration of crystalline form. The alloy of perfect arrangement is tetragonal in symmetry, and the symmetry passes by change of axial ratio into the cubic type as the temperature is raised. A similar but simpler case will be discussed here, where the arrangement of the atomic sites remains the same throughout. This is the case in the iron aluminium alloys examined in detail by Bradley.

The alloy of composition FeAl is a structure of the β type, with iron atoms and aluminium atoms at corners and centres of the unit cube. Iron has itself a body-centred cubic structure, and it is found that, when aluminium is dissolved in iron, there is a very wide continuous range of this body centred cubic phase extending from pure iron to FeAl. The added aluminium atoms simply replace iron atoms. Two types of super-lattice are built up. When the composition is FeAl, iron atoms at the centres of the cubes are entirely replaced by aluminium atoms, so that the structure is of the type known as a 'CsCl' structure. It may be noted that there is no crystallographic distinction between corners and centres, so that we might equally well describe the arrangement as one of aluminium atoms at corners and iron atoms at centres. When the composition is Fe_3Al, and the alloy is carefully annealed, one half of the cube centres chosen in a symmetrical way are occupied by aluminium and the other half remain iron atoms.

By observing the super-lattice lines in the photographs, Bradley has been able to follow out the process of replacement at all compositions between pure iron and FeAl. Taking first annealed alloys, the first aluminium atoms to enter the structure replace iron atoms at random. At a certain concentration, the aluminium atoms desert cube corners and one set of cube centres, and tend to concentrate in the remaining set of cube centres, finally at Fe_3Al occupying it entirely. Past this point, since one set of cube centres is now full, the further aluminium atoms start filling up the remaining set of cube centres. At a certain point, in order to equalise the distribution between the two sets of centres, these two share the available aluminium until finally at FeAl they are completely filled. The quenched alloys show a curious phenomenon. Up to 25 per cent atomic aluminium they have apparently random replacement. Past that point, within less than 1 per cent change in composition, they change over into a distribution in which all corners are occupied by iron, and centres by a random replacement of iron by aluminium.

RANDOM REPLACEMENT

When an X-ray photograph shows an apparently random replacement, are we to interpret this as meaning that the atomic sites are occupied by iron and aluminium as if they were the 'black and white balls' of a problem in probabilities? On physical grounds this is not to be expected. The Fe_3Al and FeAl structures show us that aluminium atoms under conditions of ideal equilibrium tend in the first place to avoid being nearest neighbours by segregating into cube centres, leaving the corners for iron, and further to avoid being in cubes which are side by side (Fe_3Al structure). We must postulate a slight increase in potential energy when aluminium atoms are at centres of contiguous cubes, and a larger increase when two find themselves at a corner and centre of the same cube. I am indebted to Dr. Williams for calculations concerned with this effect. If we suppose a small increase V of potential energy to be produced by one of these undesirable contacts, it is then possible to calculate the proportion of atoms in 'disorder' as opposed to 'order' at a series of temperatures.

The calculation shows that it is impossible to account for the whole range between complete order (which we know to exist by the evidence of super-lattice lines) and complete disorder, in any range of temperature experimentally available. The difference between annealing and quenching could at the most produce a slight disorder. The conditions we have set are, however, not true to actualities. As the structure becomes more disordered, the contrast between the ordered position and disordered position for a given atom becomes less, and so V must be supposed to diminish, until finally one can picture a state where no criterion is possible—the atom is completely demoralised by the corrupt state of society in which it finds itself.

It is possible, however, that what appears to be random replacement is not really a purely fortuitous distribution. We may suppose that within each small crystallite of the metal there is for the most part an ordered distribution, but that this ordered distribution is frequently getting 'out of step'. To take a simple case of a linear row, we may suppose an alternation Al-Fe-Al-Fe to take place for a part of the row, and that then owing to an excess of iron, two iron atoms follow, so that when the alternation recommences, aluminium and iron atoms have changed places. This process may be frequently repeated. Since the effects of all atoms in crystal planes are summed when the X-rays are diffracted by the crystallite as a whole, the result as regards diffraction would be an apparently random replacement of iron by aluminium. A kind of structural twinning within the crystal, which does not alter the orientation of its axes but only the succession of its atomic planes, is possible.

The behaviour of the quenched iron aluminium alloys suggests some such explanation. So long as aluminium is present in quantities less than 25 per cent in atomic proportions, there is apparent random replacement. Beyond this point the segregation suddenly appears by which aluminium goes into cube centres alone. May not this be because below 25 per cent the excess of iron causes the structure to get 'out of step', two successive layers of iron atoms causing a part of the crystallite with aluminium at centres of cubes to continue as a pattern in which the same atoms go to corners? Beyond 25 per cent aluminium, each cube must have contiguous cubes containing aluminium at centres, so that there is no question as to what is a centre and what is a corner. The plan of iron at corners and aluminium at centres is therefore carried out throughout the crystallite.

Though so many problems of alloy constitution are still to be solved, an important step forward has been made by the recognition that the arrangement of atomic sites and the segregation of atoms into these sites are separate problems, and by the discovery of similar phase-structures in alloy series of different metals. There is promise of reducing to order the vast array of hitherto uncorrelated data.

Medical Research in Great Britain

THE annual report of the Medical Research Council* again indicates the great variety of the scientific investigations carried out under its auspices with the ultimate aim of improving the health and well-being of the community. The scope of the research work initiated and aided by the Council has, as in previous years, been widened by grants from a number of public bodies interested in research work within the medical field, by the availability of university laboratories for use by investigators receiving grants from the Council, and by co-operation with Government departments and the committees of Privy Council for Industrial and Agricultural Research. The Council has exercised the strictest economy in the use of its available funds: the salaries of all its officers, and of all members of the scientific staff and whole-time grant holders have been 'cut' on the Civil Service scale. The reduction of various subsidies received from other public bodies imperilled the progress of different schemes of research, the abandonment of which, at the stage reached, would have been a very wasteful procedure. Fortunately, voluntary benefactions from private sources and notably those received from the Rockefeller Foundation and the Leverhulme Trustees prevented the setback in the work of the Council from being, it is hoped, more than temporary.

Three changes occurred in the composition of the Council during the year, Mr. W. S. Morrison, Prof. E. D. Adrian and Prof. A. E. Boycott taking the places of Major A. G. Church, Prof. R. Muir and Sir J. Herbert Parsons respectively.

The Council points out that the promotion of clinical research has always been given a primary place in its policy from the beginning of its work. The problem has been to find means of promoting the conditions in which clinical research work can be brought to its fullest development. With the co-operation of University College Hospital, London, the Council has maintained a Clinical Research Department there, with Sir Thomas Lewis as director, with charge of beds and free from all preoccupations except those of gaining new knowledge by clinical research. During the past year, the Rockefeller Foundation has generously provided a sum of money to endow in perpetuity the directorship of this Research Department, thereby releasing funds which the Council will apply to further clinical research elsewhere. The University of Aberdeen and the National Hospital for Nervous Diseases, Queen Square, London, have also shown their sympathy with clinical research: at the latter, a Research Department is in course of formation and Dr. E. A. Carmichael has been appointed by the Council as whole-time director.

The scope of the clinical work at University College has been widened. In earlier years the Department of Clinical Research dealt chiefly with cardiac problems and especially those of cardiac mechanism; more recently it has taken up problems of the peripheral blood circulation. At present, studies of hypertension and cardiac asthma are bringing problems of kidney function into view, and special attention is being paid to the symptom, pain. Interesting correlations between anginal pain and that derived from muscular ischæmia have been found.

The National Institute for Medical Research has continued the regular distribution of the standards held under the Therapeutic Substances Act, and of those held on behalf of the Health Organisation of the League of Nations. The international standards for vitamin A (carotene) and vitamin D (a solution of irradiated ergosterol in olive oil) were prepared in the Institute and together with the standard for vitamin B_1 (a dry adsorption product from an extract of rice bran prepared in Java) have now been issued for general use. Work has also been carried out on serum standards and a standard for Type 1 antipneumococcus serum has been prepared and issued. A review is at present in progress of different preparations coming under the general title of "Tubercle Vaccine", to ascertain the practical interpretation given by manufacturers to the regulations made under the Therapeutic Substances Act. The Institute also has obligations with regard to standards required by the new "British Pharmacopœia", other than those already held under the Therapeutic Substances Act, namely, those for digitalis, strophanthin and strophanthus tincture: the latter two were prepared during the year. A conference was held in London in July under the auspices of the Health Organisation of the League of Nations to discuss the possibility of establishing a uniform notation in units for the œstrus-producing hormone and eventually for other hormones for the reproductive functions. The conference recommended the adoption of a sample of the ketohydroxy form of the crystalline hormone as the international standard and entrusted the Institute with its preparation and distribution.

---

* Report of the Medical Research Council for the year 1931–1932. Committee of the Privy Council for Medical Research. (London: H.M. Stationery Office, 1933.) 2s. net.

The work on canine distemper by Dr. Laidlaw and Mr. Dunkin, which was aided by the *Field* fund, has now been brought to a successful conclusion. Its progress has been described in previous reports. The whole cost of the work, spread over ten years, has been about £55,000. This has been supplied by the *Field* Fund, of which about £22,000 was contributed from British sources and £15,000 from the United States, while the rest, in services of staff, and in accommodation and other facilities, has been provided by the Council from its Parliamentary grant-in-aid. A review has been made of the results of simultaneous side-to-side inoculation with anti-serum and virus. This method appears to be rather less efficient in producing a solid and durable immunity than the original vaccine and virus method.

The usefulness of this work is not limited to the prevention and cure of canine distemper. The method of using vaccine and virus has been employed for the immunisation of man against yellow fever in West Africa and is also being used for the prevention of rinderpest among cattle in East Africa. At least one type of epidemic disease in silver fox farms appears to be due to the virus of canine distemper, and should therefore be preventable by similar means.

Work has also been continued on other virus diseases of both man and animals. In addition, a series of different bacteriophages has been subjected to critical filtration through Elford's filters. The diameter of the smallest is identical with that found for the virus of foot-and-mouth disease. The largest is stopped by a filter of such coarseness as to indicate that its particles are almost within the range of microscopical detection. The size of any one bacteriophage has been found constant and uniform independently of the nature of the bacterial organism which it attacks, and it is unchanged by purification. It appears that the bacteriophages are distinct infective agents of the nature of viruses. Confirmation is found in the fact that specific immune sera can be produced to different bacteriophages by injecting them into animals.

In concluding this brief review, it may be mentioned that the report describes, amongst numerous other investigations, work on malignant disease and nutritional problems.

National Academy of Sciences Medal Awards

IT is announced by Science Service, Washington, D.C., that at the closing session of the meeting of the National Academy of Sciences held in Washington on April 24–26, the following medal awards were made: Alexander Agassiz medal for oceanography to Dr. Albert Defant, of the Institute for Oceanography, Berlin, for his studies on atmospheric and oceanic circulation and his notable contributions to theoretical oceanography; Public Welfare medal to Dr. William H. Park, of New York, for his work as head of the research laboratories of the New York City Department of Health as a pioneer and leader both in research and in the application of scientific discovery to the prevention of disease; John J. Carty medal and award for the advancement of science, a newly-established honour of the Academy, posthumously to the man in whose honour it was named, the late Dr. John Joseph Carty, who was noted for his accomplishments in the field of electrical engineering, particularly as they influenced the development of electrical communication; Henry Draper medal to Dr. V. M. Slipher, of the Lowell Observatory, Flagstaff, in recognition of his spectroscopic researches, which have opened up several important fields in astronomic research; Mary Clark Thompson medal to Dr. Francis Arthur Bather, formerly keeper of the Department of Geology, British Museum (Natural History), for his services in the fields of palæontology and geology.

AT the same meeting of the National Academy of Sciences, the following men of science were elected to membership of the Academy: Dr. Oswald Theodore Avery, Rockefeller Institute for Medical Research, known for his work in bacteriology; Harold Delos Babcock, physicist at the Mount Wilson Observatory, Pasadena; Dr. Thomas Barbour, curator of reptiles and amphibians at the Museum of Comparative Zoology, Harvard University; Dr. Alphonse Raymond Dochez, professor of medicine in Columbia University; Dr. Bernard Ogilvie Dodge, plant pathologist in the New York Botanical Garden; Dr. Eugene Floyd DuBois, professor of medicine in Cornell University Medical College; Prof. Griffith Conrad Evans, professor of pure mathematics in the Rice Institute, Houston, Texas; Bancroft Gherardi, vice-president of the American Telephone and Telegraph Company, New York City; Dr. Herbert Eugene Ives, physicist at the Bell Telephone Laboratories, New York City; Prof. Walter Richard Miles, professor of psychology in Yale University; Prof. Samuel Alfred Mitchell, professor of astronomy in the University of Virginia and director of the Leander McCormick Observatory of the University; Prof. Linus Pauling, professor of chemistry in the California Institute of Technology, Pasadena; Prof. Joseph Fels Ritt, professor of mathematics in Columbia University; Prof. Henry Clapp Sherman, Mitchill professor of chemistry in Columbia University.

Technical Training of the Police

LORD TRENCHARD'S recently issued annual report as Commissioner of Police of the Metropolis (Cmd. 4294. London: H.M. Stationery Office) has been received with mixed feelings. In all essentials, however, the case which has been made out for reorganisation is unassailable. The suggested formation of a police college is one of the recommendations to which exception has been taken, the grounds of objection being apparently that experience is the only training of use to the police officer. It is interesting to compare this point of view with that on the Continent. In Belgium, France and Germany, schools for the technical training of the police have been in existence for many years. In Belgium, for example, all policemen are required to take a short course at the school of scientific police. The course is designed to give the candidate an elementary grounding in the application of scientific methods to the detection of crime. More advanced courses up to the standard of a university degree are available for the higher ranks. In this respect the reorganisation advocated by Lord Trenchard will bring the system of police training closer to the Continental model. Having regard to the great advances which have been made in the application of scientific methods to the detection of crime in recent years, this is all to the good. It has been proved beyond doubt that the laboratories of the technical police can and do greatly assist the progress of criminal investigation. Apart from the practical work itself, a great deal of research work is done in these laboratories, which are specially equipped for the purpose. Absence of facilities has made this impossible in England, where very little investigation of this kind has been done. We may certainly hope that the implications of Lord Trenchard's report will become explicit in this direction and that we shall have a department for the scientific detection of crime.

Musk-Rats at the London Zoo

THE Zoological Society is indeed rendering a valuable service by putting specimens of the musk-rat on exhibition. By this means it is hoped to spread information of the grave menace which threatens large areas of Great Britain from the hosts of musk-rats which have insidiously appeared among us. It will be remembered that an article by Prof. J. Ritchie on this subject appeared in NATURE of March 18, p. 385. As was pointed out there, the musk-rat was originally introduced into Great Britain a few years ago to encourage 'fur-farming'; but the enthusiasts who entered into this scheme had no knowledge of the habits of the animals or of their amazing fecundity. As a consequence of bad-housing, many made their escape to the nearest rivers, or sheets of open water, where they remained unmolested amid ideal conditions for a considerable time, because their presence was unsuspected. It was not until railway embankments, dams, water-mills and the foundations of bridges were found to have been seriously damaged over large areas of the country, that the peril in our midst was realised. It has now been made illegal to import or keep musk-rats in Great Britain. The ill-advised introduction of the grey-squirrel has given abundant cause for repentance; but the mischief done by this pest is as nothing compared with the potential mischief which threatens from the musk-rat.

ANOTHER rodent of no little interest just added to the collection at the Gardens of the Zoological Society is the rock-cavy, or moco-cavy, of Brazil, a near relation of the guinea-pig. It is a cave-dweller, but boulder-strewn areas serve it quite as well, though even in those fastnesses it is eagerly pursued by the natives, who find its flesh delectable. In appearance it is more slender than the guinea-pig, with a long snout, and soft grey fur. A collection of humming-birds from tropical America, two of those remarkable reptiles, the egg-eating snakes, giant land-crabs from Gambia, and migratory locusts in the wingless, hopper-stage, are other additions adding still further to the attraction of the Gardens just now.

Zoological Society of London

THE report of the Zoological Society for 1932 impresses with the magnitude of the undertaking: a membership of 8,307, a visitors' list of more than a million and a half, an annual income of £130,403 and expenditure of £128,803, and a surplus of assets over liabilities amounting to £143,413. In spite of their magnitude the figures, compared with those of the past four years, show some effect of the present financial stress, but this has scarcely affected the steady progress made in the Gardens in London and at Whipsnade. The health of the animals has improved, a noteworthy record being the absence of any death from tuberculosis amongst the primates, whereas in 1926, 43 died from this disease alone. The architectural experiment of a new gorilla house of unique construction (see NATURE of May 6, p. 646) should contribute further to the health of animals admittedly difficult to keep in captivity. The position of the "Zoological Record" Fund has improved, but the loss on each volume is still much greater than the £500 per annum contributed by the Society, and societies, institutions and individuals who wish the "Record" to be maintained are requested to support the "Record Fund" by annual donations. Appeal is also made for contributions towards the maintenance of the famous herd of Chillingham Park white cattle, since a sum of £500 per annum is required to meet the rental of the Park at Chillingham Castle in Northumberland, which has been leased for seven years with the object of preserving the herd.

University of London and the British Museum

IN a correspondence between the Trustees of the British Museum and the Court of the University of London, published in the *Times* of May 18, the former body extends a cordial welcome and warm congratulations to the University on the acquisition of a home which will express its functions as a centre of humanistic and scientific research for Great Britain and the Empire. The Trustees touch on what everyone will recognise as an all-important element in the future development of teaching and research in the University, when they point to the opportunities for co-operation between the Museum and the University which will arise. In this connexion they refer more particularly to relations with the Institute of Archæology, for which a scheme is under the consideration of the University authorities. This will be a great step forward in the study of archæology in London. On one hand, the increased activity in archæological research of recent years and the need of trained men to take full advantage of the opportunities for archæological investigation which are now open in many directions, have for some time past made the need for an archæological institute, such as is contemplated, a matter of urgency. On the other hand, the efforts of the Museum to meet the varied requirements of the general public, the advanced research worker and the student in archæology, appreciated as they have been, have made an undue and unjustifiable demand on the energy and time of the staff. An earnest of future benefit to the University is already offered in the intimation that that very necessary adjunct of a practical training, a supply of cultural material, will be available for the Institute from the superabundance of the Museum.

Lower Thames Valley Deposits

A temporary exhibition is now on view in the prehistoric section of the British Museum, which includes a sequence of stone implements and flakes found by Mr. J. P. T. Burchell in the area between Swanscombe and Northfleet in North Kent. The exhibit illustrates Mr. Burchell's correlation of the industries with the glaciations of the Thames area, this involving a fresh interpretation of the events following the Boyn Hill Terrace deposits. Briefly, his contention is that following on the Boyn Hill or '100 ft.' terrace, with Clactonian I (abraded and striated), Clactonian II, Acheulean and early Mousterian, comes a period of elevation with pauses, causing terraces at progressively lower levels, in which are early Mousterian abraded implements, until Sunk Channel No. I was cut. These deposits were then sealed by glaciation and the deposit of Combe rock. Melt-water gravels then formed in the valleys and on the plateaux, which contain abraded implements of the above cultures. A period of elevation and aggradation and submergences followed, in which a thick layer of brick-earth with middle Mousterian implements was laid down over a wide area. There was then an elevation and an accumulation of sub-aerial deposits containing upper Mousterian and Aurignacian implements with coarse pottery. This was followed by a glaciation and the deposition of Trail and/or strong loam with 'rafts' of Combe rock, the equivalent of the Upper Hessle boulder clay of Yorks and East Anglia.

It will be seen that Mr. Burchell's interpretation differs from that of the geologists, who have hitherto regarded the Taplow or '50 ft.' terrace as earlier than the Combe glaciation. Archæologists and geologists alike have recognised the division of the Taplow or '50 ft.' terrace into a lower gravel with heavily rolled Acheulean and early Mousterian artefacts, as at Ealing and Hanwell, and an upper brick-earth, sealing floors containing unrolled middle Mousterian implements, as at Acton, Crayford, and Northfleet. Mr. Burchell finds that this sequence constitutes two distinct terraces separated by the glaciation responsible for the Combe rock. Capping the brick-earth is the glacial deposit known as the Trail. Among the exhibits are photographs of critical sections, as well as implements, in support of Mr. Burchell's view, as against that current in geological circles, that the Combe rock is to be equated with the Trail. This correlation is rejected by leading archæologists in the 'Handbook' of the Prehistoric Congress, 1932, p. 10. Mr. Burchell's discovery of coarse pottery in association with an upper Mousterian or Aurignacian industry is rendered less unorthodox by the evidence of Leakey from Kenya and Peyrony in France. The identification of extensive areas of brick-earth in the Swanscombe district containing shells belonging exclusively to land types seems to form a link with the upper loess of the Continent.

Physics in the Boot and Shoe Industry

The nineteenth lecture in the "Physics in Industry" series of the Institute of Physics was delivered by Mr. H. Bradley, director of the British Boot, Shoe and Allied Trades Research Association, on May 23, on "Physics in the Boot and Shoe Industry". A problem of first-rate importance in the boot and shoe industry is mensuration or anthropometry. How shall a foot be measured in order to specify concisely and accurately its shape ? The industry has hitherto relied on the eye and skill of handicraftsmen of the old school ; few of these now remain and there is need for a scientific method of foot specification. A useful start has been made on this investigation, and experiments with the most recently designed foot-measuring instrument have proved most successful. Measurements of the foot when stationary should be supplemented by a knowledge, either qualitative or quantitative, of the requirements of the foot in motion. As yet very little is known in this direction and experimental investigations were planned several years ago. The proposed experiments are closely allied with physiological studies. More about the change in conformation of the foot during walking is required. Furthermore, in the case of normally healthy feet the arches of which have not broken down, there are three main points of pressure, namely, under the heel, the inside joint or ball, and the outside joint ; it is necessary to know how the body weight is distributed among these several points of support and how this distribution changes during walking. For a material in common everyday use, leather has received little attention from physicists, particularly in Great Britain. The science of leather has developed during the past thirty years mainly on the chemical side from the point of view of its manufacture. A line of investigation into the physical properties of leather, which has been selected because there is a likelihood of its being profitable in two or three directions, is the reaction of leather to the influence of water both in the liquid and vapour state.

Alcoholic Fermentation

The twenty-second Bedson lecture was delivered on May 19, at Armstrong College, Newcastle-on-Tyne, by Prof. A. Harden, emeritus professor of biochemistry in the University of London, who took as his subject "Alcoholic Fermentation". Besides the president (Dr. R. E. Slade) and the chairman (Prof. G. R. Clemo), the past presidents, Prof. P. P. Bedson and Dr. J. T. Dunn, and Profs. H. J. Hutchens, Irvine Masson and H. L. Riley were present. Dr. Harden traced the history of the scientific investigation of fermentation from Lavoisier to Büchner and then outlined briefly but with great clarity the work of Neuberg, Meyerhof, and others as well as his own. He developed and reviewed the equations advanced for the process, discussed the rôle of the hexose mono- and diphosphates formed, and the co-enzymes required in yeast, muscle extracts, and bacteria. The fermentation processes leading to glycerol, the glycols, compounds of the butane series, lactic acid, and fumaric acid were all dealt with, as well as the energy relationships in muscle contraction with which these processes are linked. Finally, the differences between the actions of extracts and living cells were discussed.

Jubilee of the University of Oxford Junior Scientific Club

ON May 20, at the University Museum, Oxford, the Junior Scientific Club held a successful and largely-attended conversazione to celebrate the jubilee of its foundation. The Club was inaugurated in 1882 with the object of bringing together undergraduate and bachelor of arts members of the University for the discussion of scientific matters. The holding of conversaziones has always been an important part of the Club's activities, and special interest was attached to last Saturday's gathering in view of the fact that the Club has just passed the fiftieth year of its useful existence. Numerous demonstrations and exhibitions of scientific objects had been arranged by the Club, supplemented by some assistance from others. Among the features that excited most interest were a demonstration by Prof. J. G. Gray of the properties of gyroscopes, experiments with liquid air, phenomena of polarised light, series of insects, chiefly butterflies, illustrating the theory of mimicry and the phenomenon of seasonal change, and an exhibit of the results of a zoological survey of Bagley Wood. The Main Court, including the Pitt Rivers Museum of Archæology and Ethnology, was open throughout the evening; and a water-colour drawing by Bernard Gotch of the entrance to the Old Ashmolean, together with objects from the historic scientific collections there preserved were also on view. The guests of the Club were received by the president, Mr. D. H. P. Peel, of Merton College.

James Watt Memorial Institute, Birmingham

ON May 15, Mr. A. E. L. Chorlton, M.P., president of the Institution of Mechanical Engineers, opened the James Watt Memorial Institute in Great Charles Street, Birmingham, which has been provided out of the funds subscribed at the James Watt Centenary in 1919. The original scheme for which the funds were raised included both the endowment of a chair at the University of Birmingham and the erection of a building for the joint use of engineering societies. The sum subscribed, however, did not allow of the scheme being carried out in its entirety, and after establishing a research scholarship and defraying other expenses, the balance was placed in the hands of trustees, by whom the present premises have been leased and fitted up with a hall, committee room and library. In declaring the premises open, Mr. Chorlton reminded those present that the Institution of Mechanical Engineers had its birth in Birmingham and remarked that the Memorial Institute could not fail to contribute to progress by bringing engineers together for intercourse and discussion.

Alaskan Earthquake of April 26

ON the night of April 26, much damage was caused in several towns in Alaska by an earthquake. The epicentre, as determined by the U.S. Coast and Geodetic Survey, lay in Lat. 61° N., Long. 153° W., a point north-west of the Kenai Peninsula, the time at the origin being 9.36 p.m., eastern standard time. An interesting and unusual observation was made by Mr. Earl L. Williams at Gaithersburg, Md., 4,000 miles from the epicentre. While working in his observatory at about 10 p.m., he noticed that the bubble in the spirit level attached to his telescope was sliding to and fro with a slow, even motion (Science Service, Washington, D.C, April 27 and 28). Similar observations have been made in a few other earthquakes. For example, on May 9, 1877, about 74 minutes after the great Iquique earthquake, the Russian astronomer Nyren noticed unusual oscillations in the bubble of a spirit-level fixed to the transit instrument in Pulkova Observatory, more than 8,000 miles from the epicentre. Again, on April 4, 1905, after the Kangra earthquake, movements were observed in levels at Tando Masti Khan (Sind) and Thedaw (Upper Burma), which are respectively about 660 and 1,300 miles from the epicentre.

Fifth Pacific Science Congress

REFERENCE has already been made in these columns to the Fifth Pacific Science Congress to be held in Victoria and Vancouver on June 1–14 (NATURE, April 22, p. 581). From a report dated May 2 issued by the National Research Council of Canada, it appears that of 393 scientific papers received for presentation at the Congress, 131 have come from Japan, 101 have been received from the United States, fifty-six from Canada, seventeen each from China and New Zealand, eleven each from Australia and Great Britain, eight from the Netherlands Indies, four each from Hawaii, Mexico, Siam, and the Netherlands, three each from India and Peru, two each from Norway, Straits Settlement and Federated Malay States and Sweden and one each from Colombia, Denmark, Ecuador, Fiji, France, Guatemala, Philippine Islands and Spain. Arrangements are being completed whereby through the courtesy of the British Post Office, the Canadian Marconi Company, the Bell and British Columbia Telephone companies, a demonstration of a long distance wire and radio circuit will be made at the Congress and a speaker heard from Great Britain. Commdr. C. P. Edwards, Director of the Radio Branch, Department of Marine, Canada, is in charge of the demonstration.

World's Grain Conference

SIR DANIEL HALL, director of the John Innes Horticultural Institute, Merton, Surrey; Sir John Russell, director of the Rothamsted Experimental Station, Harpenden, Herts; and Prof. William Robb, director of research of the Scottish Society for Research in Plant Breeding, Corstorphine, Edinburgh, have been appointed by the Ministry of Agriculture to represent the British Government at the World's Grain Conference to be held at Regina, Canada, on July 21–August 4. At the Conference experts from all the chief grain-producing countries of the world will examine every aspect of the grain problem. The agenda provides for a thorough examination of the present trends of the world wheat position and the question of controlling production of wheat and other cereals. Another difficult problem to be faced is changes that may be necessary in the financing of the world wheat surpluses. Wheat import standards, improvements in merchandising and marketing and economy in transportation and storage will also be considered. In addition, various technical groups will discuss soils, seeds, fertilisers, pests, economics, harvesting, machinery and milling. A prominent position amongst the educational exhibits will be occupied by the display which is being arranged by the Rothamsted Experimental Station under the personal supervision of Sir John Russell. The exhibit will include sheaves of wheat from the 89th successive crop grown on the same field under varying conditions, and will demonstrate recent research into potato and other root crops in which Canada is now particularly interested.

World Petroleum Congress

THE international nature of the petroleum industry, coupled with numerous strides it has made during the last decade, make the holding of a Congress at this juncture desirable. The need for such a Congress on technical matters is unquestioned, particularly in view of the international discussions which have taken place in recent years concerning, specifically, nomenclature and methods of testing, and it was high time that an earnest endeavour was made to co-ordinate these discussions and bring about some measure of universal agreement. The Institution of Petroleum Technologists is in every way qualified to sponsor such a Congress and, since the proposal was first put forward and adopted, the organising efforts of the Committee have met with great success and encouragement. At a recent general meeting of the Institution, the arrangements for the Congress, which is to be held at the Imperial College of Science and Technology, South Kensington, S.W.7, on July 19–25, were discussed fully and a very comprehensive programme, dealing with all phases of the petroleum industry, was presented. Among the subjects to be reviewed are petroleum geology and production, oil collection, treatment, transport and measurement, hydrogenation, bituminous materials, refining problems, alternative fuels and international co-operation in standardisation. The Congress has been recognised by His Majesty's Government and delegates from various societies, institutions and committees concerned with petroleum technology all over the world have been appointed and will take an active part in the vital work scheduled for this Congress. Apart from the technical business of the Congress, there will be a government reception to the delegates, a lecture by Sir John Cadman at the Royal Institution, visits to works and laboratories of interest, exhibitions of films illustrating the petroleum industry at the Imperial Institute, a banquet at the Mayfair Hotel on July 24 and a number of social functions, which are now universally recognised as essential factors to the achievement of a full measure of success in undertakings of this character.

Atmospheric Pollution

THE eighteenth report of the Department of Scientific and Industrial Research on the "Investigation of Atmospheric Pollution" (H.M. Stationery Office, 5*s*. net) records observations for the year ending March 31, 1932. It shows that the co-operation of local authorities has been well maintained in spite of the financial difficulties of the times. Comparisons between towns on the basis of the tests, should, it is stated, be made with caution. A deposit gauge may be placed in a position where conditions are not truly representative, and it is the trend of the results over a period rather than the absolute weights of deposit which should be stressed. From this point of view there is evidence of improvement in the atmosphere of some provincial towns of Great Britain. This cannot be said of the deposit of tarry matter, which is "pre-eminently a product of domestic fires and there is little reason to think that the amount of smoke from domestic fires has decreased much in recent years". Deposits of sulphate have increased in some places, notably Ravenscourt Park, London. Such increase, it may be inferred, may be due to the increase in the sulphur content of the fuels burnt—some fuel oils are rich in sulphur—or to the concentration of fuel burning on one site, such as in large power stations. London does not show up well in the matter of smoke fog while Coventry again has an excellent record, ascribed last year to the use of gas for domestic and industrial heating.

International Illumination Congress, 1931

THE final report and statement of accounts of the International Illumination Congress, 1931, held in London and the provinces under the presidency of Mr. C. C. Paterson, has now been published. Upwards of a hundred papers, contributed from all over the world, were presented at the technical sessions in the provinces. Some of these papers contained important original matter that has led to much discussion. Donations amounting to more than £6,000 were received from industries, etc., connected with electrical engineering and £2,000 from the gas industry. Grants of £724 have been made for the development of illuminating engineering. The Committee states that the success of the Congress exceeded the most sanguine expectations.

New Journal of Experimental Agriculture

The publication of the new *Empire Journal of Experimental Agriculture* is, as the Minister of Agriculture states in his prefatory message in the first issue, "a natural and valuable development from the Imperial Agricultural Conference of 1927", for "in an Empire which fundamentally is founded on agriculture it is impossible to over-estimate the value of co-operative research work in agriculture". Furthermore, to quote the introductory message from the Secretary of State for the Dominions, it is of the utmost importance "to provide that those who are responsible for guiding agricultural policy shall keep in close touch with each other and shall quickly pool for the common advantage every new fruit of discovery and invention in the agricultural field". It is to meet these needs that the new journal has been published. The contents of the first number (April 1933) indicate that all types of problems dealing with crop or animal husbandry will lie within the scope of the journal. Subjects such as soil investigations in Canada and Cyprus, nutrition of sheep and dairy cows, animal disease, grassland management, haymaking machinery, Canadian wheat breeding and residual values of crops are dealt with, and, as an interesting contrast to the problems of to-day, an account of grain growing in Kent in the thirteenth century is included.

Announcements

At the annual general meeting of the Linnean Society of New South Wales, held on March 29, Prof. A. N. St. G. H. Burkitt, Challis professor of anatomy in the University of Sydney, was elected president for the ensuing year.

At a meeting of the Linnean Society of London, held on May 24, the following were elected foreign members: Dr. Elmer D. Merrill, director of the New York Botanical Garden; Dr. Erwin Baur, director of the Kaiser-Wilhelm Institute of Genetics, Müncheberg; Prof. Adolf Pascher, professor of botany in the German University, Prague; and Prof. Filippo Silvestri, professor of genetics and agrarian zoology, Portici. Mr. F. J. Killington and Mr. Thomas Sheppard were elected associates of the Society.

Prof. H. S. Taylor, David B. Jones professor of chemistry in Princeton University, was presented with the Mendel medal of Villanova College, Pa., U.S.A., on May 4. The Mendel medal was founded by the Augustinian fathers of Villanova College in 1928 to commemorate the well-known work of Gregor Mendel. It is awarded annually to "a Catholic who has signally advanced the cause of science". Prof. Taylor has been associated with chemistry at Princeton since 1914, and was appointed David B. Jones professor in 1927. He was made a fellow of the Royal Society in 1932, and is the author of numerous papers dealing especially with catalysis and the mechanism of chemical reaction. In collaboration with Prof. E. K. Rideal he wrote "Catalysis in Theory and Practice" and he is also the editor of a "Treatise on Physical Chemistry".

The twelfth annual conference of the Institut International de Documentation (formerly de Bibliography) will be held at Brussels on July 18–21. A series of lectures is being arranged and visits to institutions in the neighbourhood will be a feature of the programme. Further information can be obtained from the Secretary, British Society for International Bibliography, Science Library, South Kensington, London, S.W.7.

Applications are invited for the following appointments, on or before the dates mentioned:—A headmaster of the Sheffield Junior Technical School for Boys—The Secretary for Education, Education Office, Leopold Street, Sheffield (May 31). A domestic science mistress at the Polytechnic, Regent Street, London, W.1—The Director of Education (June 2). A lecturer in electrical engineering at the Kingston-upon-Hull Municipal Technical College—The Director of Education, Education Offices, Guildhall, Hull (June 3). An inspector of technical schools and colleges either in electrical engineering or chemistry (fuel technology)—The Director of Establishments, Board of Education, Whitehall, London, S.W.1 (June 3). An assistant lecturer in education at University College, Hull—The Registrar (June 9). A teacher of domestic economy (cookery and dietetics) at the Belfast Municipal College of Technology—The Principal (June 10). An assistant lecturer in physics in the University of Manchester—The Registrar (June 16). A professor of physiology at the University of Birmingham—The Secretary (June 12). An assistant lecturer in botany at the University of Bristol—The Registrar (June 17). A professor of metallurgy at the University College of South Wales and Monmouthshire, Cardiff—The Registrar (June 17). Instructor lieutenants in mathematics, science and engineering in the Royal Navy—The Adviser on Education, Admiralty, S.W.1 (July 1). Three research bacteriologists in the Medical Research Department of the Government of India; a professor of biochemistry and nutrition, a professor of malariology and rural hygiene (including venereology and tuberculosis) and a professor of vital statistics and epidemiology, and an assistant professor of public health administration, an assistant professor of biochemistry and nutrition, an assistant professor of malariology and rural hygiene (including venereology and tuberculosis), and assistant professor of vital statistics and epidemiology, at the All-India Institute of Hygiene and Public Health, Calcutta—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (July 1). A city engineer and surveyor for Capetown—Messrs. Davis and Soper, Ltd., Agents of the Corporation, 54, St. Mary Axe, E.C.3 (July 5). A research worker and a civil engineer for the Malaria Survey of India—The Secretary, Indian Research Fund Association, Simla, India (July 31). A lecturer in biology at the Stockwell Training College for Women, London, S.W.9—The Principal. An assistant in the Department of Domestic Science of Battersea Polytechnic, London, S.W.11—The Principal.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Scales of Loudness

IN the course of an extensive investigation into the measurement of noise, it became clear that the accepted standards of sensitivity of the human ear both on a basis of absolute pressure and subjective loudness needed revision. Previous work on this subject has been largely directed towards telephone conditions of listening, whereas in the more usual case of listening under 'free space' conditions, other factors such as the collecting power of the outer ear, and diffraction of the sound waves by the listener's head are involved. In order to obtain representative data, measurements have been made on 48 people of the just inaudible sound pressures at typical frequencies. All the subjects were of normal hearing and the pressures were those measured by a microphone of accurately determined field calibration in the absence of the subject. The figures given in Table I are the modes of the results and, therefore, refer to the most probable values. The subjects were chosen to represent both sexes and ages from fifteen to sixty-five years.

TABLE I

Frequency	100	200	400	800	1,600	3,200	6,400
Pressure R.M.S. Dynes/ Sq. cm.	0·0036	0·0018	0·00040	0·00023	0·00020	0·00020	0·00097

The unsatisfactory nature of the loudness scale based on the law of the logarithmic sensitivity of the ear, and conveniently embodied in the decibel scale, became obvious during experience with the method of assessing noise in terms of the intensity of an 800 cycle note which appears equally loud. By expressing the results in decibels above the threshold of audibility at 800 cycles, the figures should, by the above law, be proportional to loudness. Experience gained on the measurement of a great variety of noises shows this is not so; for example, the relation between two noises assessed in this way at 90 and 45 db. is judged by the average person to be that one is much more than "twice as loud" as the other. Since this aural comparison of loudness is so common and is, indeed, the final criterion of any scale of loudness, measurements were made on 30 people to determine what meaning, if any, could be attached to the estimate "twice as loud". The results were surprising in that, in spite of misgivings on the part of the subjects, the results were quite concordant. This result was in agreement with that obtained over a more restricted range by Ham and Parkinson[1] who also gave a reference to a paper by Richardson and Ross[2]. After preliminary measurements, the normal range of intensities at 800 cycles was covered in steps of 2 : 1, starting from 100 db., which was called 100 on the loudness scale. What is perhaps more surprising is that the curve obtained with 4 : 1 steps agreed very well with that derived from the 2 : 1 steps. Table II gives the final average figures for the relation between decibels above the threshold at 800 cycles and loudness deduced from these 2 : 1 and 4 : 1 estimates.

TABLE II

Db. above Threshold at 800 cycles	0	49	58·5	68·5	80	87·5	94·5	100	104·5	108	110
Loudness	0	5	10	20	40	60	80	100	120	140	160

An alternative loudness scale constructed as suggested by Kingsbury[3] by integrating the minimum detectable intensity changes, redetermined at 800 cycles for free space conditions, while being better than the simple decibel scale, was much less in accordance with mental estimates than the above.

To make the loudness scale apply to other frequencies the equal loudness contours determined by Kingsbury were redetermined for free space conditions, and his figures, obtained with a telephone, found to be applicable. His results were extended to 6,400 cycles and up to 100 db.

Several years' experience with the 800 cycle comparison tone method of assessing noise intensities has shown that it is most reliable, particularly for fairly steady noises, assessments by different individuals being usually to within ± 2 db. A suitable 800 cycle valve oscillator, direct reading attenuator, and single headphone have been developed in easily portable form, and this apparatus has been used to measure a great variety of noises both in the laboratory and in particular places such as streets, buildings, etc. The attenuator reads directly in decibels but the above table enables the corresponding loudness figures to be determined.

An account of the development of this apparatus and the determination of the above tables from the physical, psychological and practical points of view will be published in the near future.

Diffraction of Electrons in Amorphous and in Crystalline Antimony

A THIN layer of antimony was deposited on a film of cellulose nitrate by evaporating in high vacuum. The specimen was then examined by electron diffraction in transmission. It was mounted in such a way that it could be rotated about an axis lying in the plane of the film and perpendicular to the electron beam. The following results were obtained and could be repeated at will:

When the metallic deposit is not too thick (showing weak or medium absorption of light) the diffraction pattern (Fig. 1, *a*) shows that the structure is amorphous. Numerous tests with other metals and blank films exclude the possibility that the pattern observed may be due to a cause other than the deposit of antimony.

If the deposit is very thin, the amorphous state remains absolutely unchanged for an indefinite time (at least for six months); electronic bombardment seems to have no influence. In the case of medium thickness, crystalline spots appear after some time and within a couple of hours the whole film shows a crystalline structure (Figs. 1 *b* and *c*) agreeing perfectly with the results of X-ray analysis[1]. As shown by the figures, the crystallites are not oriented at random but tend to arrange themselves so as to form a single crystal having its rhombohedral axis normal to the surface of the film[2]. Sometimes after crystallisation the amorphous state persists at the edge of the film where the thickness of the deposit is least. The crystallisation seems to set up strains in the film as it often breaks afterwards and scarcely ever before. It may be added that the deposit shows a metallic lustre in the amorphous state as well as after crystallisation.

With thick deposits (strong absorption of light) only the crystalline structure was observed. It may be pointed out, however, that in this case the films often crack some seconds or minutes after the evaporation has finished. From this it is inferred that the deposit is probably still amorphous for a short time after condensation.

I may be allowed to emphasise that in the case of Fig. 1, *a* the state should be considered as truly amorphous and not colloidal. This is based on the fact that the diffraction pattern is sensibly the same with different specimens and at different times. Crystallisation is either perfect or absent. Moreover, the diffraction pattern of the amorphous state shows little analogy with a 'broadened' powder diagram of crystalline antimony. On the other hand it agrees well with that to be expected from a packing of spherical monatomic molecules as in a liquid[3]. It is well known that in this case the 'grating constant' *d* (calculated by putting into Bragg's law the value of the diffraction angle for the first maximum) is related to the mean intermolecular distance *a* by the formula:

$$d = \alpha a$$

where α is a constant which Keesom[4] puts equal to 0·81, but which by a more rigorous treatment[3] and by considering the strong decrease of the scattering of electrons with the diffraction angle, would come out slightly higher (perhaps 0·85). As shown in the papers quoted, the value of *a* in A. is approximately:

$$a = 1{\cdot}33 \left(\frac{M}{D}\right)^{1/3}$$

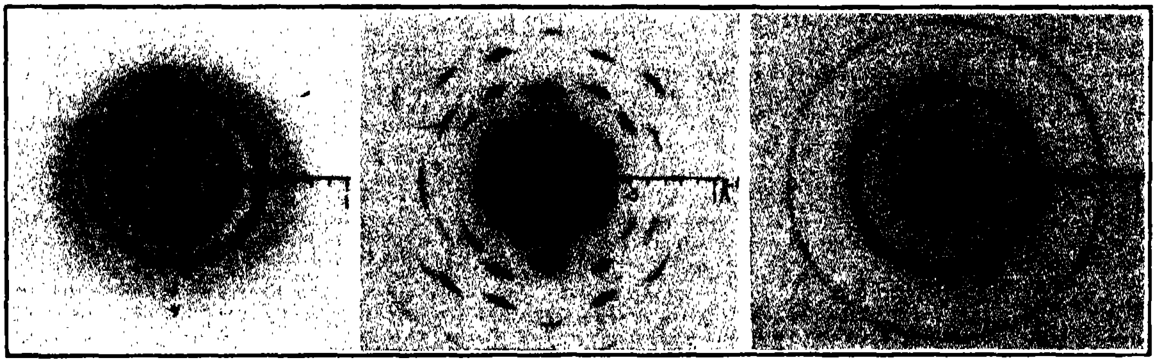
where *M* is the molecular weight, *D* the density of the substance. Now crystalline antimony has a density 6·7 and as melting does not influence the value appreciably, it seems reasonable to use the same value for our amorphous antimony. The formulæ then yield:

$$d = 0{\cdot}85 \times 3{\cdot}47 = 2{\cdot}95 \text{ A.}$$

in excellent agreement with the experimental value given below.

In the present investigation, four subsequent 'maxima' of decreasing intensity were observed. The corresponding values of d^{-1} and *d* are given below:

Maximum	1 (strong)	2 (medium)	3 (weak)	4 (weak)
d^{-1} (in A.$^{-1}$)	0·335	0·514	0·679	0·791
d (in A.)	2·99	1·94	1·47	1·26



(*a*) (*b*) (*c*)

FIG. 1. Electron diffraction patterns in antimony.

(*a*) Amorphous; $\theta = 45°$. (*b*) Crystalline; $\theta = 45°$. (*c*) Crystalline; $\theta = 0°$. Diffraction of electrons (40–50 kv.) in antimony. The normal of the film makes an angle θ with the direction of the electron beam (axis of rotation vertical). The scale indicates the reciprocal grating constants d^{-1} calculated from Bragg's law; $\lambda = 2d \sin \varphi$.

A measurement of the intensities sufficient for a calculation of the frequency curve[5] for the intermolecular distance could not be made.

Influence of Light on Paramagnetic Susceptibility

THE so-called 'photomagnetic effect' was first described by Bose and Raha[1] as a decrease in the paramagnetic susceptibility of chromic chloride and of several other salts on exposure to light. Later the same authors corrected themselves[2] and claimed an increase in susceptibility followed by a slow decrease. Specchia[3,4] and Gorter[5] have also investigated the effect, the former finding a slight increase followed by a slow decrease, while the latter found only the decrease. None of these workers states the sensitivity of the apparatus used, although Specchia, who used the capillary rise method, says that water gave a deflection of 3,000 scale divisions.

I have investigated the effect in solutions of ferric chloride, chromic chloride, and neodymium nitrate by a method similar to that described by Decker[6]. In this method a small rod (test-piece) is suspended between the pole pieces of the magnet and the couple acting on it is a function of the difference in volume susceptibilities of the test-piece (K_0) and of the surrounding solution (K_1). In order to eliminate errors from variations in field intensity the test-piece was made of glass filled with gadolinium oxide so that $K_0 = K_1$. The apparatus was sensitive to 0·005 per cent, apparently about four times less sensitive than Specchia's apparatus. The light sources were a 100 watt microscope lamp, and a carbon arc. Cupric chloride solution was used to filter out the infra-red. The results obtained in every case confirmed those of Gorter; no increase was observed, but a slow decrease took place. The temperature increase due to radiation absorption was about 0·0002° per second, which was roughly that expected to cause the observed decrease in susceptibility. A marked movement of the test-piece occurred on exposure to light from which the infra-red had not been thoroughly screened off. This was doubtless due to a radiometer effect. It could be almost eliminated by making the light path strictly parallel to the test-piece.

It may be worth mentioning that the explanation of the increase in susceptibility given by Bose and Raha[7] seems to be open to the following objection. They suggest that the light causes a temporary breakdown of the l-coupling between paramagnetic ion and associated solvent molecules, thereby reducing the orbital moment damping. Such a mechanism could scarcely give rise to their observed increase of the same order of magnitude in didymium salts, as in say ferric chloride, because in the former case the $4f$ electrons which are responsible for the paramagnetism are almost completely screened from external influences, while for elements of the first transition series the orbital moments are usually strongly if not completely damped by the electrons of neighbouring ions or molecules.

Supersaturation of Liquids with Gases

ALTHOUGH it is well known that liquids may be supersaturated with gases, the *extent* to which a gas may be retained in supersaturated solution does not seem to be generally realised, and no quantitative information about the phenomenon is given in most textbooks on physical chemistry.

We recently had occasion to repeat some experiments by E. C. Gilbert[1] on the oxidation of hydrazine by potassium ferricyanide, in which the course of the reaction was followed by measuring the rate at which nitrogen gas was evolved. The velocity constants obtained were much higher than those recorded by Gilbert at the same temperature and with the same initial concentrations of reagents. It was found that the rate of evolution of gas was controlled mainly by the rate of stirring, increasing with the latter up to about 1,000 r.p.m. (The rate of stirring in Gilbert's experiments was 250 r.p.m.)

That this result was due to supersaturation of the aqueous solution by the nitrogen produced in the reaction, and not to genuine variation of the reaction rate with stirring, was shown by allowing the reaction to proceed for some time in unstirred solution, and then stirring vigorously. Rapid evolution of gas occurred, and the total volume evolved soon equalled that which would have been obtained if the solution had been stirred from the beginning. In some cases the amount of nitrogen which accumulated in the unstirred solution was seven or eight times the normal solubility of the gas.

Since the course of many reactions is followed, in quantitative work on chemical kinetics, by noting the rate of evolution of a gaseous product, it is important to emphasise the fact that supersaturation, unless broken down by adequate means, is likely to invalidate completely results obtained in this way.

The extent to which supersaturation may occur in solutions saturated with gases under pressure has already been demonstrated in papers which appear to have received less attention than they deserve.

K. S. Wyatt[2] found that an aqueous solution of nitrogen, saturated at a pressure exceeding 100 atmospheres at air temperature, could be brought to atmospheric pressure without the immediate formation of bubbles in the liquid, and F. B. Kenrick, K. L. Wismer, and K. S. Wyatt[3] obtained similar results with oxygen, nitrogen and carbon dioxide. J. Metschl[4] investigated the supersaturation of water and various organic solvents with oxygen, nitrogen, hydrogen and carbon dioxide at five atmospheres pressure, and found that the resulting solutions were very stable at atmospheric pressure, vigorous agitation being required before all the excess gas could be removed. Metschl's paper contains references to earlier work on the subject, mostly of a qualitative nature.

When a solution is supersaturated with a solid, introduction of a crystal of the solid immediately induces crystallisation, but in the case of a solution supersaturated with a gas, the presence of bubbles of the gas is not similarly effective. For example, in the oxidation of hydrazine by ferricyanide, gas is slowly but continuously evolved, even when the solution is unstirred, without breaking down the supersaturation.

Further work is being carried out on this reaction.

Alkylanilines with Tertiary Alkyl Groups

THE preparation of alkylanilines containing *tertiary* alkyl groups by the reaction of *tertiary* alkyl halides with aniline is known to present serious difficulties. Thus Nef[1] obtained only a poor yield of *tertiary* butylaniline in this way and his attempts to prepare *tertiary* amylaniline furnished only an impure product. By using suitable modifications of Nef's method, it has been possible to obtain *tertiary* butylaniline, *tertiary* amylaniline and *tertiary* hexyl aniline in a state of purity.

An examination of the reactions of these amines has revealed some surprising abnormalities. The tertiary alkyl group is split off by heating the amines with aqueous mineral acids. This type of fission takes place more readily with the aryl sulphonyl derivatives of the amines. Thus while *tertiary* butylaniline is converted into aniline to the extent of 50 per cent by heating it with 15 N sulphuric acid at 120°–140° for 14 hours, the p-toluene sulphonyl derivative of *tertiary* butylaniline yields more than 90 per cent of the p-toluene sulphonyl derivative of aniline when it is heated with 15 N sulphuric acid for 1 hour at 135°–145°. The experimental evidence so far obtained indicates that the readiness with which the alkyl group is split off by the action of hot diluted sulphuric acid is in the order *tertiary* butyl $<$ *tertiary* amyl $<$ *tertiary* hexyl.

It has also been observed that the free amines do not react readily with acetic anhydride or with aryl sulphonyl chlorides. On the other hand, methyl iodide reacts with tertiary butylaniline fairly readily. Some of these reactions appear to find an explanation on the electrochemical theory recently elaborated by Robinson[2].

A detailed account will be submitted for publication elsewhere shortly.

Higher Homologues of Sulphur Hexafluoride

IN fractionally subliming solid sulphur hexafluoride at low temperatures, we have noticed that the last fraction liquefied before vapourising. The vapour was obtained in a fairly pure state after repeated fractionation and its density was determined with a microbalance. As fractionation proceeded, the density rose rapidly from approximately 73 (that of sulphur hexafluoride) to the neighbourhood of 125, at which it remained steady. A new sample of sulphur hexafluoride was then prepared and a further quantity of the heavy constituent obtained. Two density determinations carried out independently by each of us on different microbalances and with different samples, gave values of 126 and 129.

From these figures it is evident that the gas has a molecular weight of about 256 and is probably S_2F_{10} (molecular weight 254). During the preparation of the sulphur hexafluoride the air present in the apparatus was previously displaced by nitrogen. Hence the possibility of contamination by oxygen compounds was excluded. Moreover, the gas was allowed to stand over concentrated potash for a long period before fractionation, so that the new gas resembles sulphur hexafluoride in not being easily hydrolysed. Its boiling point is in the vicinity of 0° C. We have also obtained, in very small quantity, a volatile oil, immiscible with and unattacked by water, which may be a still higher homologue of sulphur hexafluoride.

We are proceeding to analyse these compounds and to investigate their properties.

Inheritance of Intelligence in Man

IN a recent paper[1] Dr. C. C. Hurst has discussed the inheritance of intelligence in man. After adverting to the fact that the data of Galton and Woods show that general intelligence in adults grades continuously from high to low both in general and in selected populations, Dr. Hurst finds it convenient to adopt ten grades of intelligence, because some of the data he uses is already so graded. He regards as a special *non-segregating* type those families which consist only of Grade 5 (mediocre) offspring whatever the grades of the parents, while he is content to classify as *segregating* a family of four Grade 4 (dull) offspring of parents themselves both of Grade 4.

Grade 5 is certainly peculiar, as will be seen at once from the frequency distribution of some of the data which is plotted upon permille paper in Fig. 1. The grading is stated to be equivalent to that of Galton except that the number of grades is reduced by compressing into Grade 5 six of Galton's grades, (C, B, A, a, b, c). It is just because these grades are merged into one that so many families consist only of Grade 5 offspring. These *non-segregating* families are a product of the system of grading and it is difficult to follow Dr. Hurst when he states that "the gradings are naturally imperfect . . . but, taken as a whole, the results show a general agreement which . . . signifies a close approximation to reality."

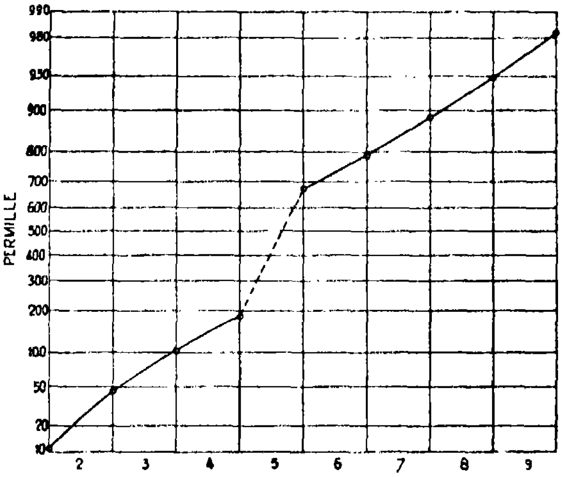

FIG. 1. Frequency distribution for R.F. data.

Dr. Hurst proceeds to develop a basic genetical formula for the inheritance of natural intelligence. This development, also, appears to be highly arbitrary, for by using three grades only a much simpler formula would surely emerge, while forty grades would yield a formula no less portentous than, and possibly quite as useful as Dr. Hurst's hexagenic one, with its 729 genotypical forms. It may perhaps be remarked that it seems somewhat lavish to postulate 729 genotypical forms in a hypothesis framed to justify ten discrete grades of intelligence.

A. F. DUFTON.

Greenbank, Garston,
Hertfordshire.
April 1.

---

[1] *Proc. Roy. Soc.*, B, **112**, 80; 1932.

In placing major and minor genes on an equal footing, Mr. Dufton has failed to realise the modest rôle played by modifiers in a genetical formula. Had he worked out the formula, he would have discovered that the 729 genotypes produce only seven different kinds of effective gametes, so that the formula is not so complex as he imagines and is thus more effective in predicting the inheritance of intelligence than he realises.

The statement that the special non-segregating families have parents of any grades is obviously incorrect. Reference to Tables II, IV, VII and IX of my paper shows that each non-segregating family has a Grade 5 parent, since it is those that are being tested.

It is suggested that the non-segregating families are merely a product of the system of grading and that if mediocrity had been divided into six grades instead of one, there would have been no non-segregating families. An examination of the tables of data shows that this inference has no foundation in fact. So far as the non-segregating families are concerned, it is immaterial whether mediocrity is graded in six grades or one; the fact remains that they produce mediocrity only and no higher or lower grades of intelligence. So far as the segregating families are concerned, the grading of mediocrity in six grades would produce in Tables III, V, VI, VIII, X and XI an aberrant and abnormal frequency curve making the results unintelligible both statistically and genetically.

After many years' trials and tests in my investigations of the Leicestershire families, I found it impossible to divide mediocrity into grades with any certainty. On the other hand, it was usually easy to distinguish the adjacent higher and lower grades from mediocrity since they differed in kind rather than in degree. The intelligence quotient (*I.Q.*) tests of children carried out also confirmed this discontinuity of mediocrity. For those reasons, Woods's ten grades were adopted and his data utilised, the eleventh, grade 0, being added as a necessary sequence of the formula.

It is realised that, like other scientific formulæ, the present formula is only tentative, representing as it does the present state of knowledge. But it is basic and it is clear that no simpler formula would cover the present data. Human intelligence is not so simple a matter as Mr. Dufton would have us believe, and it is now too late to attempt to account for its inheritance on the basis of a single Mendelian difference.

The alternative suggestion that forty grades would be quite as useful, may be nearer the truth than Mr. Dufton imagines, although the facts available do not warrant such a conclusion. Further research with more refined and precise methods of grading will no doubt increase the number of grades and the number of minor genes concerned. It is doubtful, however, whether any subdivisions of the present grades would affect the basic discontinuity between stable *NN* mediocrity and *nn* higher unstable and lower grades.

Recent research indicates that more important developments may be expected from a comparative study of the modifying genes for general intelligence (Spearman's *g*) and those for the special faculties (Spearman's *s*). There is evidence, for example, that the modifiers of general intelligence (*nn*) also act as modifiers of musical ability (*mm*), and the question arises whether these same modifiers also act as modifiers of other special faculties.

C. C. Hurst.

Cambridge.

A Possible Property of the Positive Electron

The detection of the positive electron (called positron) by Blackett and Occhialini[1] and by Anderson[2] makes it very probable that the positron has a great importance in the building up of nuclei. Anderson[2] suggests that the proton may consist of a neutron and a positron. In favour of this hypothesis we may mention the experiments of Stern (still unpublished), who found that the magnetic momentum of the proton is three times greater than it should be if the proton were to behave like an elementary particle in Dirac's theory. Following Heisenberg[3], both the proton and the neutron obey Fermi statistics and have a half integral spin momentum. This leads at once to the conclusion that, if the hypothesis of Anderson is true, the positron should obey Bose statistics and have an integral spin momentum (0 or 1). If this view should be confirmed by other experimental evidence we should understand better why the positrons can only be found in nuclei; for, since positrons have symmetrical wave functions, they can always be placed in the deepest energy levels. It seems to be an advantage of the proposed hypothesis, that contrary to Dirac's theory of 'holes'[4] an essential asymmetry between positive and negative electricity is introduced into the laws describing the behaviour of elementary particles. Since the light-quanta also have whole number momenta, it seems that it may be a general rule, that symmetrical wave functions are combined with integral momenta and anti-symmetrical wave functions with half integral momenta.

Recent Magnetic Disturbances

A very notable magnetic disturbance—the greatest recorded at Stonyhurst for more than four years—occurred on April 30–May 2, the greatest movements being between noon and midnight on May 1. The 'storm', as it may fairly be called, began with a typical 'sudden commencement' at 16h. 27m. G.M.T. on April 30, when declination suddenly fell 2′ and then rose 6′, whilst horizontal force fell 36γ followed by a rapid rise of 75γ. No important movements followed until about 21h., when a 'bay' formed in both *D* and *H*, lasting about four hours, after which conditions were quiet until about 13h. on May 1, when the greatest movements began to manifest themselves, and the disturbance ended almost as abruptly as it began at about 1h. on May 2. The range in *D* was 60′ and in *HF* 436γ, ranges which have not been exceeded since 1929 Feb. 27–28.

It is noteworthy that there had been no spots on the visible hemisphere of the sun since April 21, when a small but active group, which passed the central meridian on April 20, died out. If this spot group is in any way associated with the magnetic disturbance, on the theory of emission from the sun of particles which reach the earth's atmosphere, the time of transmission of these particles, presumably emitted when the disturbed area was on or near the central meridian of the sun, would be ten or eleven days, and their velocity 175–150 km. per second.

Another recent disturbance which seems to suggest the possibility of a long-deferred activity associated with a spot group occurred in February. On that occasion the largest spot group which had appeared for more than two years, and showed considerable activity, passed the central meridian on February 7, and disappeared at the west limb on February 13, without any accompanying magnetic disturbance. Thereafter the disc was completely free from spots until February 27. On February 19, however, a very notable magnetic disturbance commenced, which for six consecutive days ranked as 'great', and for a further three days as 'moderate' in the Stonyhurst system of characterisation. In this instance the time interval between the central meridian passage of the spot group and the commencement of the magnetic disturbance was twelve days, and that to the maximum range, which occurred on February 21, was 14 days; if a physical association between the two is assumed, this would imply particle velocities of 150 km. and 125 km. per sec. respectively, which are of the same order of magnitude as those postulated in the more recent disturbance, and are moreover of the order of radial velocities which have been observed spectroscopically in prominences and dark hydrogen flocculi.

Hitherto, it has been considered that the most probable interval between the occurrence of a spot group on the central meridian and an associated magnetic storm is about one and a half days, with a range of from two days before to four days after the central meridian passage[1].

An interval of 1½ days implies a velocity of transmission of the particles of about 1,200 km. per sec., and this interval seems well established for cases in which the association of spots and storms is fairly obvious. But the possibility of an association in particular cases at much longer intervals does not appear to be ruled out, and if such an association can be proved, it might go far to clearing up much of the obscurity which still remains as to the relation between terrestrial magnetic conditions and solar phenomena. The present time, when with the approach of sunspot minimum the solar conditions are much simplified, is an eminently suitable one for carrying out such an investigation.

The problem, however, is not simple, for if it be admitted that particles with so low a velocity as, say, 120 km. per sec. may be responsible for the production of magnetic disturbances, then there seems no reason why particles with any velocity between this and the maximum attainable may not be productive of disturbance, with any interval up to 14 days between the central meridian passage of the disturbed solar area and the associated magnetic disturbance. If it is found that the length of observed interval does not vary continuously throughout its range, but tends to be grouped round certain values, there would be an indication that the particles concerned tended to have certain specific velocities, perhaps related to their size, or to the wave-lengths of light responsible for the radiation pressure to which their velocities may be attributed.

A Destructive Lightning Flash

ON Tuesday, May 9, at 3.40 p.m., a single destructive flash of lightning came to earth on my property at St. Marybourne, Andover, doing freakish damage there besides blowing very many of the electric light fuses in the village and 'blowing up' fourteen telephone boxes. The lightning struck a tree and a wire fence about 100 yards from the house but the charge of current in the local 230 volt village circuit was such that the fuses were not merely blown but those in my house made of copper 26 s.w.g. blew out the asbestos packing and deposited bright metallic copper all over the inside of the porcelain covers. A wireless set that was connected to the lighting circuit and to a well exposed aerial was not damaged at all even though there was no earth connexion to the aerial. A proper lightning guard is now in place. In my absence, the wireless set was not actually turned on; had it been, more things might have happened.

The more freakish incidents, however, occurred where the lightning actually struck. The tree struck is a black Italian poplar about 50 feet high then bursting into leaf, but there are no visible marks higher than about 20 feet. Below this there is a narrow score down one side and on the other a great area of the tree is stripped bare and the bark thrown about. The tree stands 7 feet away from a wire fence put to protect a 3-year-old quick fence from the cattle, and there is a similar wire fence 7 feet beyond. At a point 30 feet up the hill from the tree there is a laburnam straining post and about 15 feet from this post is the nearest corner of an American wind pump with galvanised iron tower and galvanised sails. This stands 35 feet high and would appear to have been an excellent route for the lightning to earth, but it was not touched. The top of the straining post where a branch of the lightning evidently struck was blown to pieces and the bits scattered for about 30 feet. This post was split down to the ground but the lightning left it at the bottom wire 18 inches above the ground and made this red-hot, burning off the zinc as far as the tree. There the strained wire broke and the lightning smashed the oak post at this point breaking it clean in half and splitting both ends. The three intermediate oak posts are undamaged except for being scorched by the red-hot wire.

At the foot of the smashed post a big flint put there to help steady it showed a mark which attracted the attention of Mr. F. H. Mackintosh, a well-known geologist, who thought it due to the lightning, and when I tried to lift the flint up the upper half came clean away from the lower half. A number of small flints also showed clean new fractures. This post, No. 4 from the start, was 7 feet from the tree and the flash dug a trench between in the turf about two feet wide and one deep, throwing the earth and sods as much as twenty feet away, and two sods were left in the tree about 12 and 15 feet up.

It so happened that my gardener, Mr. Waters, was standing at the door of the house and was looking that way at the time as he did not like the look of the cloud; he saw the earth and stones thrown up like a shell-burst and as they fell a cloud of dark smoke and steam blew away. Almost immediately after the flash there was a deluge of rain of very short duration—0·03 inch all told. This no doubt started before but was overtaken by the flash. Some of the bark was combed into a fine matted fabric and nearly black. Some of these fell 50 to 60 feet away but the short sharp wind may have helped them to travel. A second trench was dug through the quick fence to the further wire fence.

About 100 yards of the fence was badly damaged. Continuing down the hill the 9th post was broken clean through below the bottom wire but posts 5, 6, 7 and 8 were not touched, nor were posts 10, 11, 12, 14, 16, 18, 21, 22, 23. Posts 13 and 15 showed slight damage near the ground but post 17, which had been an oak gate post, was split from the top wire to the ground. Posts 19, 20, 24 and 25 showed slight damage near the ground. This fence went on another 100 yards to the river but no more posts showed any damage.

Going up the hill from the straining post much the same sequence of damaged and undamaged posts was found. Perhaps it may be worth mentioning that post No. 16, 100 feet from the straining post, had the top broken clean off and below the bottom wire the post was split open so badly that the one part was nearly free.

Only ten minutes before cows had been lying round the mill but fortunately they had been taken away to be milked.

The whole village was properly scared by the flash which seems to have been of exceptional violence, and they were expecting me to come and dig up the thunderbolt.

Photographic Graticules

IN the annual report of the Department of Scientific and Industrial Research, 1932–1933, par. 4 on p. 111, dealing with the work of the British Scientific Instrument Research Association, gives the impression that photographic graticules were not produced in Great Britain previous to the investigation carried out by the British Scientific Instrument Research Association to which the paragraph refers. This arises as the result of certain excisions which I made for the purpose of reducing the draft drawn up by the British Scientific Instrument Research Association to a length suitable for its inclusion in the Report of the Department of Scientific and Industrial Research. I had no intention, in abbreviating the draft, of rendering it open to being read so as to convey this wrong impression.

In fairness to Mr. Julius Rheinberg, I should like to direct attention to the fact that he did great service to the optical industry during the War by developing the manufacture, by his firm, of large numbers of graticules required in instruments for Service purposes, and that his firm has been regularly supplying "grainless" and "filmless" photographic graticules since that time, though I learn that production of the latter variety has now been discontinued. I am the more sorry that the excisions should have made the paragraph capable of giving rise to the impression mentioned above since, on one occasion at my personal request, Mr. Julius Rheinberg undertook the production of graticules of a particular kind needed for a new type of instrument which had just been developed by a British manufacturer who had failed to obtain satisfactory graticules of that type from any other source.

An Oestrogenic Substance from Plant Material

IN a recent communication[1] A. Butenandt mentions the identity of animal follicular hormone with the substance found by him also in plant material. In this connexion I should like to take the opportunity of presenting the results of my researches, which will appear shortly in full in the *Bulletin* of the Polish Academy of Sciences.

From 65 kgm. of the female flowers of the willow I obtained a semi-crystalline substance having a strength of 35,000 m.u. of the follicular hormone. After the further extraction of this original preparation with 60 per cent ethanol and benzene, more than 11,000 m.u. were found in the benzene fraction. From the alcoholic solution I obtained by G. Marrian's method 7·5 mgm. of crystals, the properties of which were identical with the properties of trihydroxyoestrin prepared by me from female urine. The microscopical aspect and the solubility in various solvents of the two substances were in both cases very similar; the absorption spectrum in the ultraviolet and the melting point of the acetyl derivatives (126°) being identical. By mixing crystals of the willow preparations with crystals of trihydroxyoestrin from urine (m.p. 277°) the melting point of the urine preparations was lowered only 1°.

The substances differ, however, in their biological activity, which in plant material was about 1,000 m.u. in 1 mgm., whereas in the purest preparations of trihydroxyoestrin from urine I have found the activity to be 4,000 m.u. in 1 mgm. (aqueous injections in five doses, each 0·2 c.c. in 36 hours). From the mother liquid after the crystallisation of trihydroxyoestrin, a yellow substance in the form of small particles separated, the activity of which was about 1,800 m.u. in 1 mgm. The small quantity of this substance prevented, however, its further examination.

Detection of Traces of Carbon Monoxide in Air

IN NATURE for March 25 and May 6, pp. 441 and 654 respectively, it has been pointed out that carbon monoxide can be detected in air (1) in proportions of 0·015 per cent by the palladium chloride solution method, and (2) in proportions of 0·004 per cent by the Hartridge reversion spectroscope.

While palladium chloride papers have been used here to this order of accuracy, the iodine pentoxide method is used when the detection (and measurement) of still smaller proportions is required; it has been claimed[2] that 10^{-6} grams of carbon monoxide can be detected as iodine in this way. Such sensitivity has not been required here; we have, however, used this method to detect one part in 200,000 (0·0005 per cent), and find it suitable for routine use.

Research Items

Burmese Spirit-World. In *Man* for April, Maung Htin Aung describes certain beliefs relating to spirits held in Burma. Spirits are of many kinds, but fall into two main divisions—the higher, which are worshipped, and the lower, which are not. The former are Buddhist, or pre-Buddhist which became semi-Buddhist on the introduction of that religion into the country, among them being 'the thirty-seven Nats'. The lower spirits have not yet been described in detail. Of them there are three kinds. The commonest, the *ah-sain-tha-yè*, are 'ghosts' which wish to hurt and frighten human beings. There are four grades, of which the lowest, the *hmin-zar*, appear in the form of small animals, darting out of the darkness. If one of these runs around a man three times completely, he will die in seven days. The *tha-hsè* appear in various forms and make noises. The *tha-yè* and the *tha-bet* do not differ greatly and are more powerful than the *tha-hsè.* They can inflict physical injury and prefer human flesh to the meat which satisfies the first two grades. Witch masters give these spirits meat regularly to have them as servants; but if they then fail to supply the meat, they are liable to be attacked. The *ót-ta-sount* guards hidden treasure, its power varying with the value of the treasure. It does not harm human beings unless they attempt to take the treasure. The *kyat* is totally harmless, and lives in holes in the ground, coming out at night to feast and laugh the whole night through. They are kindly and often entertain travellers at their feasts. All these spirits, being forms of evil, are frightened by religion and piety. When a spirit is troublesome, it may be driven away by summoning a monk to recite prayers, or a master of magic to exercise his art against it or by an offering made to the Nats, who order the spirit to leave, or by appealing to an administrative officer, who orders it not to interfere with the King's subjects on pain of exile. A spirit is powerless to disobey an order of exile from the Crown.

Mesolithic Culture in Palestine. Three communications in the *Journal of the Royal Anthropological Institute*, vol. 62, pt. 2, deal with the mesolithic period in Palestine, which was unknown before the investigations therein described. Miss Dorothy Garrod describes the excavation of the caves of Shukba and Mugharet el-Wad, Mr. Turvile Petre that of the cave of Mugharet el-Kerbarah, and Miss Dorothea Bate reports on the animal remains from the caves, in so far they throw light on the mesolithic fauna of Palestine. The stratification of the two caves excavated by Miss Garrod was much involved. In the Shukba cave the strata extended from Byzantine to Mousterian. At Mugharet el-Wad, the outer chamber showed remains of all ages to Arab times in inextricable confusion, while the inner chamber had an undisturbed sequence of four strata of upper palæolithic. The terrace of this cave, however, showed from recent to bronze overlying a mesolithic stratum with two subdivisions, which corresponded with a clearly marked typological differentiation. The evidence from the two caves points to a distinctively characterised microlithic culture, precisely like nothing previously known, and therefore distinguished by the name 'Natufian', divisible into a Lower (Mugharet el-Wad *B.*2) and an Upper (Mugharet el-Wad *B.*1 and Shukba). A tentative dating 5000–4000 B.C. is suggested. At Mugharet el-Kerbarah, Mr. Petre found a comparable culture which was particularly rich in worked bone. It resembles the Lower Natufian of Mugharet el-Wad and represents the earliest phase of Natufian yet known. Miss Bate reports that many forms well represented in the cave deposits have become much rarer or have disappeared in the modern fauna. Such are a horse, a large ox or buffalo, and the spotted hyæna. There is nothing to suggest domestication, though the Natufians were acquainted with agriculture. In Mousterian times the deer was the predominant form; by Mesolithic times the gazelle was predominant. This points to a change of climate from moist to dry and inferentially from a wooded to open country.

Reptiles and Amphibians of the Pacific Islands. In connexion with their description of the reptiles and amphibians collected in the Pacific Islands by the Whitney South Sea Expedition during the years 1920–30, Charles E. Burt and May Danheim Burt discuss the geographical relationships of the fauna (*Bull. Amer. Mus. Nat. Hist.*, 63, art. 5, Dec. 1932). The reptiles and amphibians on the islands of the Pacific Ocean are obviously derived from East Indian elements, which in turn show strong Asiatic and Australian affinities. The fauna of the South Sea Islands has been derived from New Guinean (or Papuan) elements and its eastward migration seems to have taken place through the Solomon, Banks, Santa Cruz and New Hebrides groups to New Caledonia and the Loyalty Islands in the west and to the Fiji group and points still closer to America in the east. That this distributional pathway has been made use of by the oriental fauna as a whole, is indicated by the progressive and continuous reduction in the number of species inhabiting the more distant areas. It has even resulted in a few instances in the transplantation of oriental forms into the New World. Chance dispersal has been very common in this distributional pathway, which has been determined by the linear order in which the greater land masses are arranged.

Night Migrations of *Schistomysis* and *Pseudocuma*. In a short paper ("Quantitative Studies Between the Tide Marks", *Glasgow Naturalist*, 1932) Mr. Richard Elmhirst, superintendent of the Scottish Marine Biological Station, Millport, gives some interesting information as to the abundance of some common animals of the beach. He shows that there is a set of tidal migrants which invade sandy shores after darkness. These include several amphipods, the mysid *Schistomysis spiritus* and the cumacean *Pseudocuma cercaria.* In hauls taken in February 1932 at the water's edge in a sandy bay, *Schistomysis* was found in quantities near low water at 7.30 p.m. with the moon obscured. At 5 a.m. at low water with the moon shaded there were only a few left but a large number of *Pseudocuma* had taken their place. Neither species was abundant at 10 p.m. when the moon was clear and the tide rising. Thus *Schistomysis* apparently left the shore when the moon was clear and was later replaced by *Pseudocuma.* Further hauls on different occasions show that these two species do not usually occur together but are found at different times of night or in the early morning in the same place. On the other hand, several amphipods were taken with *Pseudocuma*, especially at midnight. The proportions of the sexes were different at different times, adult females of *Schistomysis* occurring more frequently at 9 p.m. or midnight than in the early morning.

Aristogenesis. In a communication to the National Academy of Sciences, Washington, on April 25, Prof. Henry Fairfield Osborn defined the term "aristogenesis", which he had proposed at the meeting of the British Association in 1931. It is to be used as a descriptive term, without theoretical significance, and implies the orderly creation of something better or more adaptive, as observed when tracing series of fossils through successive ages. The new characters which tend towards betterment, arise independently in widely separated geographical areas, at the same or different aristogenic rates. They are definite secular changes, rather than the changes due immediately to new habit or environment which were noted by Lamarck. They were studied by Waagen in evolving series of shells of fossil mollusca, and by Osborn himself in the grinding teeth of successive fossil mammalia. The new characters which Osborn formerly named "rectigradations" may now better be termed "aristogenes". They develop more slowly than the "allometrons", or changes in the proportion of parts.

Spray Spreaders. The days belong to the past when a fungus attack was combatted by spraying infected plants with a fungicide only. Modern spray fluids contain a 'spreader' or wetting agent in addition to the fungus-destroying or insect-killing substance. A very useful survey of the various substances which can be used as spreaders and their chemical actions with some fungicides and insecticides appears in the 1932 Year Book of the Horticultural Education Association (vol. 1) entitled "The Present Uses and Future Development of Spray Spreaders" by Hubert Martin (pp. 76-84). The author deals first with the action of spreaders, and then discusses the various classes of substances used to this end. Soap was the first, and is, perhaps, still the most widely used spreader, but it is shown to have many limitations. A new method for its preparation from fatty acid and dilute alkali is described and shown to require less labour of preparation than the standard method of making a stock solution. The newer spreaders—sapamines, agrals and sulphite lye—are described and by-products from oil refinement and oils themselves can also be used. The special question of spreaders for sulphur and the new idea of using a spreader for Bordeaux mixture are also discussed. The article is of great interest to all scientific horticulturists.

Volatile Transport of Silica. In a contribution on this subject from the Geophysical Laboratory at Washington by J. W. Greig, H. E. Merwin and E. S. Shepherd (*Amer. J. Sci.*, Jan. 1933, pp. 61–73), experiments are described showing that if the volatiles that are driven off from rocks when they are heated are under a small pressure, transfer of silica through the vapour phase is brought about at an important rate. In the absence of water or other volatiles, under conditions otherwise identical, the transfer was found to be too slow to be appreciable by the methods adopted. In the experiments, which were conducted at constant temperature, silica was vapourised from the inner surface of sealed bulbs of silica glass and deposited on platinum as crystals of crystobalite. When the temperature was high, crystobalite formed a continuous crust on the inner surface of the tubes. It was found that even a small pressure of the volatiles produces a striking effect in inducing crystallisation in certain silicate liquids. This phenomenon may be applied to prepare crystals in glass for the study of equilibrium relationships in cases where it would otherwise be extremely difficult to grow crystals. The various deposits of crystobalite are described and illustrated by eight photomicrographs.

Magnetic Data and Mine Surveying. In a paper read before the Institute of Mine Surveyors (Staffordshire and Warwickshire Branch), on April 8, Mr. T. G. Bocking directed the attention of mine surveyors to certain phenomena of terrestrial magnetism which have a practical bearing on the accuracy with which precise magnetic surveying may be carried out. For accurate surveys, it is essential in the first place that the degree of magnetic disturbance occurring during the process of surveying should be known, and for the use of mining engineers, the *Colliery Guardian* and the *Iron and Coal Trades Review* publish every week tables provided by the Royal Observatory, Greenwich, and the Meteorological Office, which give, by means of appropriate symbols, a measure of the disturbance in magnetic declination as recorded at Abinger and Eskdalemuir respectively. The ideal conditions for magnetic surveying are obviously at times of little or no disturbance, and Mr. Bocking points out the possibility of forecasting favourable periods by making use of the well-known tendency of magnetic disturbance and magnetic calm to recur at intervals of about twenty-seven days, equivalent to the synodic rotation period of the sun. In 1918, Dr. C. Chree, in a paper read before the Institution of Mining Engineers, pointed out that there is decidedly more than the average chance that a day which follows about twenty-seven days after a disturbed day will show more than normal disturbance and, conversely, that a day which follows about twenty-seven days after an international 'quiet' day will show less than normal disturbance. Using the daily Abinger magnetic data, Mr. Bocking constructed a chart covering the period April, 1928–March, 1933, by arranging the daily symbols successively in horizontal rows of 27. The recurrence tendency becomes at once apparent by well-marked groupings or sequences of similar symbols. Mr. Bocking advocates that in Great Britain magnetic surveying should be carried out between 10^h and 14^h G.M.T.; during these hours his analysis shows that a small percentage only of magnetic disturbances occur and, in addition, the rate of change of the diurnal variation of declination is then usually least.

Low Temperature Research. The "Reports and Communications" made by the Kamerlingh Onnes Cryogenic Laboratory at Leyden to the First International Committee of the International Refrigeration Institute at the Sixth Congress held at Buenos Aires in the summer of 1932 have been issued as a separate volume of 460 pages by Ijdo of Leyden. Under the head of thermometry, Prof. Keesom reports that the coefficient of increase of pressure with temperature for helium has been found to be 0·0036609 by the Leyden and 0·0036606 by the Berlin observers, the normal boiling point of oxygen −182·977° and −182·965°, of hydrogen −252·754° and −252·780° C. by the two laboratories, that Leyden is not prepared to accept the international scale of the resistance thermometer as defined by the Paris agreement of 1927, that for resistance thermometry at helium temperatures a phosphor-bronze is best and that thermo-electric couples of gold with 1 per cent cobalt and silver with 1 per cent gold are most suitable. Other communications deal with vapour pressures of hydrogen and helium, specific heats, speed of sound, a bibliography of thermodynamic diagrams for refrigerants, magnetic susceptibilities, and the effects of low temperatures on organisms.

Latitude Variation of Cosmic Rays. A. H. Compton has published (*Phys. Rev.*, March 15) the results of an elaborate co-operative investigation into the geographical distribution of cosmic rays. Seven sets of ionisation chamber apparatus were constructed and measurements were made at 69 stations. The ionisation due to the cosmic rays was compared with that due to a γ-ray source, and measurements with different thicknesses of lead shielding allowed corrections to be applied for local γ-rays. The ionisation plotted against barometric pressure (including therefore both altitude and 'barometer effect') lies on a smooth curve for any one latitude, but the ionisation curves for high latitudes lie definitely above those for more equatorial regions. At sea-level the change in intensity from the highest to the lowest latitude was 14 per cent, at 4,400 metres it was 33 per cent. The change with latitude was more consistent when plotted with reference to the earth's pole of uniform magnetisation. The shape of the curves is in excellent agreement with the theory of Lemaître and Vallarta, which considers the effect of the earth's magnetic field on electrons coming from remote space, and a well fitting curve is obtained by assuming that a considerable portion of the ionisation at high latitudes is due to electrons with energy about 7×10^9 volts. It appears that the variation cannot be due to the magnetic deflection of particles within a few hundred kilometres of the earth, and it seems likely that the primary cosmic rays consist at least in part of charged particles. These experiments are apparently the first to give any systematic information about the primary cosmic rays as distinguished from the secondaries which they produce. (See also NATURE, May 20, p. 713.)

Energy Absorbed in the Cold Working of Metals. Rosenhain and Stott, working at the National Physical Laboratory, have measured the evolution of heat produced by drawing down a wire in a diamond die (*Proc. Roy. Soc.*, April). The wires were of copper and of aluminium and the drawing was carried out continuously with the die immersed in a calorimeter full of oil. The tension in the wire was measured by passing the wire to and from the die over pulleys connected to electrically-indicating spring balances. The results indicate that the heat liberated is less than that equivalent to the work performed, so that some energy becomes latent in the deformed metal. Since this energy is measured as a small difference on a rather small quantity of heat, the accuracy of measurement is not high, and the differences in the manner of working the metals make it impossible accurately to compare the values with those of other workers. The order of magnitude of the values is, however, the same as that obtained by Farren and Taylor, who used a bar stretched in a testing machine.

Astronomical Topics

Astronomical Notes for June. There is a close conjunction of Mars and Jupiter at 9 p.m. on June 4, Mars being 15′ south of Jupiter; the planets will be above the horizon in England until after midnight. On the evening of June 8 there is a conjunction of Mercury and Venus, Mercury being about a degree north of Venus. The planets will be low down, but it may be possible to observe them. Saturn may be observed in the morning hours, but its south declination of nearly 17° is a hindrance to accurate work.

The sun reaches the solstice, and summer commences, at 9 p.m. on June 21.

No occultations are visible in London under favourable conditions.

Absorption of Light in the Galaxy. Several astronomers have in recent years expressed the opinion that the amount of absorption of light by scattered matter in interstellar space is greater than that previously assumed, and in consequence that the ordinarily accepted distances of remote objects need reduction. A Science Service bulletin of April 19 gives an outline of work being carried on by Prof. Joel Stebbins and Dr. C. M. Huffer at Washburn Observatory, Madison, Wis. They conclude that there is more matter in interstellar space than that embodied in the stars themselves, and that we probably do not see even to the centre of our galaxy, much less to the farther side of it. The suggestion has already been made that the dark obscuring cloud in the Sagittarius region may hide from us the bright central region of the galaxy, which may be conjectured to exist from the analogy of the great nebula in Andromeda.

Variation of Latitude. The Cookson floating telescope, lent by Cambridge Observatory to the Royal Observatory, Greenwich, has now been in use there for three periods of seven years. The period of seven years is that in which the curve of latitude variation is expected to repeat itself, as its principal components have periods of 14 and 12 months. A large diagram, showing the variations for 21 years, is reproduced in *Monthly Notices of the Royal Astronomical Society* for March. The first seven years show the largest amplitude, attaining nearly 0·30″ in each direction. In the second period it is smaller, barely exceeding 0·20″. At the end of the second period and the beginning of the third there are four years, 1925–28, in which the variation barely reaches 0·10″. After that it revives somewhat, though not reaching the amplitude of the first period. As Sir Frank Dyson describes it: "The natural period had been damped out and a fresh start was made in the second half of 1929".

The same issue of the *Monthly Notices* contains a paper by Dr. J. C. Dobbie, investigating the effects of tidal displacements of the vertical on latitude variation. Some recent work by Dr. H. Stetson suggested that this might amount in magnitude to 0·09″, which would be an important fraction of the whole variation. Dr. Dobbie's investigation, which makes use of the Michelson-Gale experiment on tides in pipes, gives a much smaller value, barely reaching 0·01″, which is practically negligible. It is inferred that the effects noted by Stetson arise from some other cause.

Vitamin Content of Butters

BUTTER is an important source of vitamins A and D in the diet, but the amounts present vary with the feeding of the cow and also, in the case of vitamin D, with the amount of sunlight to which the animal is exposed. Summer butter is more potent than winter butter. Since much of the butter consumed in Great Britain is imported, it is essential to know whether it can compare in vitamin value with the home-produced article and whether storage has any influence upon its potency. Experiments carried out during the past few years by Crawford, Perry and Zilva on Australian, New Zealand and English butters add to our information on this subject.*

The tests were carried out on young rats: for vitamin A assays they were given a diet deficient in this vitamin, but containing irradiated hardened vegetable oil, dried yeast and lemon juice to supply vitamins D, B and C respectively. When growth had ceased, small doses of butter were given daily for four weeks and the growth rate compared with that of other animals supplied with 3–5 drops of cod liver oil daily. For vitamin D tests the animals were kept on McCollum's rachitogenic diet No. 3143: the prophylactic method was used and the positive controls were given 3–5 drops of cod liver oil daily. All the animals were killed after 28 days and the ash content of the dried fat-free bones of the hind-legs estimated. The ratio of ash to organic residue was worked out and the degree of protection from rickets expressed as a percentage of the protection given by the cod liver oil. Three doses of butter were usually employed, 0·1, 0·2 and 0·6 gm. daily, and six rats were put on each dose.

The English butters tested were obtained in winter from cows stalled but also given up to 8 oz. cod liver oil a day. 0·1 gm. daily produced about as good growth in the depleted rats as the dose of cod liver oil given to the positive controls, whilst 0·6 gm. daily gave almost complete protection from rickets. The butters were retested after 5–20 months storage at −10° to −12° C. There appeared to have been some loss of vitamin A after 20 months', but no, or only slight, loss of vitamin D after 5 months', storage.

Summer and winter butters from New Zealand and two summer butters from Australia were examined. The latter were as potent as the English butters, and the New Zealand summer butter was not significantly less active. The New Zealand winter butter, however, contained less vitamin D than the others. Storage at a low temperature for periods up to two years had little effect on the vitamin content of those butters: the New Zealand summer butter showed some loss of vitamin D in this time.

Further conclusions from this research are that the breed of the dairy herd, the district in which it is pastured, and the process of neutralising acid creams before churning, have no effect on the vitamin content of the butter from Australia and New Zealand. Butters from these Dominions therefore may be recommended to fill deficiencies in the home supply. The preface to the report states that imports from Australia and New Zealand have already increased from 20 per cent of our total imports in 1913 to 44 per cent in 1932.

---

* Medical Research Council. Special Report Series, No. 175: Vitamin Content of Australian, New Zealand and English Butters. By M. E. F. Crawford, E. O. V. Perry and S. S. Zilva. (London: H.M. Stationery Office, 1932.) 1*s.* net.

University Statistics of Great Britain

THE tabular statements compiled annually by the University Grants Committee from returns submitted by universities and university colleges in Great Britain and published by H.M. Stationery Office* are models of what such publications should be—lucid, comprehensive, concise. Here is set out on twenty pages a conspectus of fifty-five institutions, comprising all important aspects susceptible of statistical presentation. The tables are preceded by a brief introductory note directing attention to some salient features of the returns with comments on their significance.

Students are classified according to sex, domicile, dwelling place (hostel, lodgings, home) during term, age on admission, grade, subjects of study, degrees and diplomas obtained. Of the total number of full-time students (35,751 men and 12,759 women) in attendance in 1931–32, approximately 23 per cent were in London, 21 per cent in Oxford and Cambridge, 21 per cent in the provincial universities of the midlands and northern England, 23 per cent in Scottish universities, 6½ per cent in Wales and 5 per cent in Bristol, Reading, Southampton and Exeter. Some 4,400, nearly 10 per cent, came from abroad, that is, from homes outside the British Isles, as did likewise 1,500 (more than 10 per cent) of the part-time students. Of these 5,900 visitors from abroad, more than half (2,609 full-time and 726 part-time) were from countries within the British Empire, whilst 1,741 full-time and 775 part-time students were foreigners. The following table gives the numbers of full-time students from abroad at those seats of learning to which they resorted in the greatest numbers and the ratios of such visitors to the total numbers of full-time students in attendance:

	(1) B.E. overseas	(2) Foreign countries	(1) and (2)	Per cent of total
London	1116	607	1723	15
Univ. Coll. ..	230	131	361	18
Sch. of Economics	133	168	301	37
Imp. Coll. ..	177	47	224	22
King's Coll. ..	121	59	180	12
Medical Schools ..	300	132	432	13

* University Grants Committee. Returns from Universities and University Colleges in Receipt of Treasury Grant. Academic Year 1931–32. Pp. 26. (London: H.M. Stationery Office, 1933.) 1*s.* 3*d.* net.

At a time when world economic problems and the quest of internationally acceptable solutions have assumed the tragic urgency of riddles of the Sphinx, it is interesting that more than a third of the London School of Economics students were from abroad and more than a fifth from foreign countries. The Imperial College (of Science and Technology) justified its name by drawing 17 per cent of its students from the outlying parts of the Empire. The number of such students at Oxford was smaller than at Cambridge, notwithstanding the imperial mission assigned to Oxford by Rhodes as the *alma mater* of the Rhodes scholars from the dominions. The large proportion of foreigners at St. Andrews and Birmingham is noticeable.

Closely associated with the question of the resort to our universities of students from abroad is the pursuit of advanced studies in them. Of the total number of full-time students 2,399 (7 per cent more than in the previous year) were engaged in research or other advanced studies and they were congregated chiefly at London (Imperial Coll. 241, Univ. 234, King's 131, School of Economics 118), Cambridge (372), Oxford (241), Edinburgh (145), Manchester (139), Birmingham (83). Part-time advanced students were numerous at London (Univ. Coll. 192, Birkbeck 178, School of Economics 99, King's 84, Univ. Coll. Hosp. Medical School 80), Liverpool (217), Glasgow (105).

University libraries are confronted everywhere at the present time with the difficulty of coping with the increasing number and cost of periodicals. The returns disclosed the fact that last year the ratio between expenditures on the purchase of periodicals and of books respectively rose from 2 : 5 to more than 3 : 5. The University Grants Committee points to the danger lest "What we may call the 'Periodicals interest' may by force of circumstances become so firmly established that it will in effect succeed in securing for itself the first call on limited library funds, and that only what is left over after its demands have been met will be available for the purchase of books proper."

University finances seem to have stood the strain of hard times well, thanks to timely limitation of commitments and concentration upon essentials, and the deficits of all the institutions, ten in number, of which the expenditure exceeded income amounted only to just over £11,000. The largest of these lapses (it was at Aberdeen) was but £3,684.

Fundamental Laws of Optical Rotatory Power

THE February issue of the *Berichte der deutschen chemischen Gesellschaft* contains an interesting account, by Dr. Werner Kuhn of Heidelberg, of a theory of optical rotatory power which he has developed with conspicuous success in recent years. A mathematical treatment of the problem has also been worked out by Dr. Kuhn and was published three years ago in the *Transactions of the Faraday Society*.

It is pointed out that in spite of the general application of the principle that optical activity is associated with structural dissymmetry, attempts to predict the magnitude or even the sign of the rotation of a new compound are singularly unsuccessful, and a more complete knowledge of the physical aspects of rotatory power seems to be necessary for a better understanding of this elusive problem. Kuhn appears to have recognised that absorption bands in the visible and ultra-violet regions constitute the physical equivalents of the asymmetric molecule of the chemist. Each of these bands furnishes a definite contribution to the rotatory power, which is the algebraic sum of all such contributions, though some of these may be negligible in value. Thus the observed rotation is in reality an additive function and each individual part of the molecule may contribute its quota.

In 1896, Cotton showed that the rotatory power of optically active compounds becomes abnormal in the region of absorption and that it is associated with circular dichroism. Now circular dichroism is caused by the unequal absorption of *d*- and *l*-circularly polarised light. Kuhn has developed this idea and has shown that a quantitative relation exists between circular dichroism and rotatory power; that is, either of these values can be calculated from the other, as illustrated by the case of chromium potassium tartrate dissolved in a solution of potassium hydroxide. Cotton investigated this solution in the visible region. In 1931 Kuhn and Szabo re-determined the values for both properties and extended their observations also into the ultra-violet region of the spectrum.

Still more striking evidence is furnished by the much more complex case of β-octyl nitrite, which Kuhn and Lehmann described in 1932. Here the curve of circular dichroism consists of several undulations and is partly positive, partly negative. From this highly complex curve a correspondingly complex curve of rotatory dispersion has been calculated and the values which are thus obtained are shown graphically to approximate very closely to experimental results.

Thus the rotatory power is the sum of the positive and negative contributions of several bands, which in the visible region are nearly but not completely balanced. Now general absorption is due to the presence in the molecule of chromophore groups, but optical rotation is not produced unless the electronic vibrations in a chromophore group are coupled with those of another group (which is probably non-absorbent or colourless), in such a way that when one vibration proceeds, say, from left to right, the other proceeds from back to front. Coupling of two vibrations in this fashion produces a difference in the absorption of *d*- and *l*-circularly polarised light and therefore dichroism, which in its turn gives rise to optical rotatory power. Thus in order that an absorption band may contribute rotatory power, it is essential that the electronic vibrations originating from a chromophore group should be capable of transmission to another part of the molecule; and the effect is greatest when this chromophore group lies near the 'centre of asymmetry'. Should these bands lie in the visible or early ultra-violet region of the spectrum, the effect on rotatory power will be very marked.

The author also deals with the vicinal effect on rotatory power of chemical changes near the absorption band. This aspect of the problem forms the subject of a separate contribution by Dr. K. Freudenberg.

University and Educational Intelligence

Cambridge.—An election to the Isaac Newton studentships will take place early in the Michaelmas Term 1933. These studentships are for the furtherance of advanced study and research in astronomy (especially gravitational astronomy, but also including the other branches of astronomy and astronomical physics) and physical optics. Those members of the University are eligible for the studentship who have obtained a degree in the University and were less than twenty-five years of age on January 1, 1933. The studentship will be of the value of £250 and will be tenable for three years. Candidates are invited to send in their applications to the Vice-Chancellor between October 10 and 16.

The Raymond Horton-Smith prize for 1931-32 has been awarded to Dr. J. E. Semple, of Corpus Christi College.

The Council of the Senate recommends that the rooms in the Forestry School when vacated by the Department of Forestry be assigned to the Department of Geography.

It is recommended by the General Board that an additional University lectureship be established in the Department of Geography, and additional University demonstratorships in the Departments of Chemistry, Physiology, and Zoology.

Dublin.—Sir Charles Arthur Kinahan Ball has been appointed Regius professor of surgery in succession to the late Sir William Taylor. Sir Arthur is a fellow of the Royal College of Surgeons in Ireland, and has been senior surgeon to Sir Patrick Dun's Hospital since 1922, as well as being honorary consulting surgeon to several other institutions in Ireland.

Mr. John Purser has been appointed professor of civil engineering in succession to Prof. David Clark. Mr. Purser is assistant professor of civil engineering in the City and Guilds (Engineering) College, and reader in civil engineering in the University of London.

Leeds.—Dr. W. MacAdam has been elected to the chair of clinical medicine as from the beginning of next session and Dr. R. H. Evans has been appointed lecturer in civil engineering.

It has been decided to institute a part-time course in biology leading to a diploma. The course will occupy six hours a week (three hours in the evening and three on Saturday morning) and will extend over two sessions. It is designed particularly to meet the needs of teachers who want a qualification in this subject.

The University Council has accepted most gratefully from Mrs. Graham of Headingley a gift of £1,200 for the endowment of a scholarship in memory of her husband, Dr. James Graham, who was for twenty-five years director of education in the city of Leeds. The scholarship will be open to candidates whose parents live or have lived in Leeds, and who have attended an elementary or secondary school in Leeds for at least three years, provided that they have passed either the matriculation or the Higher School Certificate examination prior to enrolment at the University. Preference will be given to a candidate desiring to proceed to a degree in commerce.

London.—Mr. C. A. Mace, since 1930 head of the Department of Experimental Psychology in the University of St. Andrews, has been appointed University reader in psychology (Bedford College).

The title of University reader has been conferred on the following in respect of posts held at the Colleges indicated: biochemistry, Dr. Katharine H. Coward (College of the Pharmaceutical Society); chemistry, Dr. David C. Jones (East London College), and Mr. Bryan Topley (University College).

The Dunn exhibitions in anatomy and physiology for 1933 have been awarded respectively to Mr. J. C. B. Bone (Middlesex Hospital Medical School) and Mr. J. S. Horn (University College).

Manchester.—Prof. I. M. Heilbron has accepted an invitation to a chair of organic chemistry in the University. Prof. Heilbron was born in Glasgow, and received his early education in that city at the High School and the Royal Technical College, of which institution he was a lecturer from 1909 until 1914, and, after the War, professor of organic chemistry. He was appointed to the Heath Harrison chair of organic chemistry in the University of Liverpool in 1920, and has held that post to the present date. He is known for his researches on natural products, especially fish liver oils, fat soluble vitamins, cholesterol and other sterols, and was elected to a fellowship of the Royal Society in 1931.

Dr. John Prescott, lecturer since 1905, and, since 1922, head of the Department of Mathematics in the College of Technology, retires at the end of the present session. Mr. James Winterbottom, director of spinning in the College of Technology, also retires; he has been on the staff of the College since 1894.

Dr. R. W. Gurney, at present assistant lecturer in physics in the University, has been appointed research fellow in the University of Bristol.

Reading.—The Council of the University has appointed Mr. R. Rae to be professor of agriculture in succession to Prof. S. Pennington, who retires in September. Mr. Rae is at present professor of crop and animal husbandry in the Queen's University, Belfast.

The twenty-fourth Conference of the Association of Teachers in Technical Institutions is to be held at Lincoln on June 3–6. All meetings will be in the Technical College. The arrangements have been in the hands of a committee of the Association's Leicester Branch (Joint Hon. Conference Secretaries—Messrs. T. E. Hartley, and M. Brewitt, Technical College, Lincoln). The first public meeting will be held on June 5, when the Conference will be officially welcomed by the Mayor of Lincoln (Alderman J. W. Rayment), and the retiring president, Mr. S. H. Moorfield (Mining and Technical College, Wigan), will induct the president for 1933–34, Mr. F. H. Reid (Technical College, Paddington). Resolutions on the following topics, among others, will be discussed by the Conference: regional co-ordination of technical education; increase in number of technical institutions and extensions; education and industry; junior instruction and junior unemployment centres; closure of junior technical schools; recruitment for industry. An exhibition of books and apparatus will be held in the Technical College during the Conference.

Calendar of Nature Topics

Persia, "Wind of 120 Days"

In the Persian province of Seistan a violent wind from between north-west and north-north-west sets in every year about the end of May or early in June and blows almost without cessation until about the end of September. From its duration it is known as the "Bad-i-sad-o-bist roz" or "wind of 120 days". It sometimes reaches a velocity of more than 70 miles an hour, and carries a great quantity of sand and dust, which have remarkable effects. In some places the whole land surface is eroded, and old buildings are eaten away and undercut near the ground. Elsewhere the sand is deposited in wandering dunes, which overwhelm villages and choke water-supplies. All buildings, both ancient and modern, are built with blank walls on the windward side; this wind appears to have been a regular feature of the climate of Seistan since early historic times.

The Cuckoo's Call

"On the first of June
The Cuckoo changes her tune."

It has been suggested that the change referred to in the old rhyme is the singing of a triple instead of the usual double note, but this is probably an individual peculiarity, since there are birds also which can sing only *cuck*. It is more likely that the reference is to a change which takes place in the tune itself. In the spring, the cuckoo begins singing with an interval of a minor third; about June, it is said to proceed to a major third; and later to a major fourth, then a fifth, after which its voice breaks before reaching a minor sixth.

"Der Kuckuck drauf anfing geschwind
Kuckuck! sein'n G'sang durch Terz, Quart, Quint."

The cuckoo's note itself has given trouble to the recorders. Gilbert White's neighbour, "who is said to have a nice ear", found that it varied in different individuals; "for about Selbourne wood, he found they were mostly in D; he heard two sing together, the one in D, and the other in D sharp, which made a disagreeable concert." Some he heard in C. Hoffmann says that the German folksongs mostly pitch the song in G major, which makes the song too deep. The English rhyme quoted above attributes the song to the female bird, but although the female sings and is even said to have a call of her own, the male is the most persistent caller.

Display of Sage Grouse

Amongst the many remarkable displays of birds, associated with the courting season, one of the most striking is that of the sage grouse (*Centrocercus urophasianus*), a native of the sage-brush region of western North America from southern British Columbia to New Mexico. In Oregon, R. Bruce Horsfall found the cocks assembling on May mornings by the shore of Klamath Lake, strutting with puffed-out chests and spread tails, and making noises which reminded him of the popping of corks on the pier at Atlantic City (this was in 1918). The strut was made up of four movements. First, the filling of air sacs enormously expanded the throat pouch to the accompaniment of a grunting sound; second, a short stiff-legged run was made with neither pouch nor wings touching the ground; *third*, the bird stopped suddenly, spread his tail and pushed forward his wings so as to raise the air pouch well up on the chest; fourth, a sudden upward throw caused the air pouch to rise and descend upon the chest with a rubbery 'plop', which was repeated three times before the whole performance recommenced (*Zoologica*, 2, 243; 1920). As many as sixty sage cocks were seen displaying at intervals of twenty-five to fifty feet, for each bird appeared to have a select territory on which no other dared to trespass with impunity. The display was not altogether a courting action, because when hens wandered through the throng during the performance, no notice was ever taken of them.

Barracuda Fisheries

During the month of May, the Barracuda fishery of California, which for six months supplies the markets of Los Angeles, reaches its height. Occasional fish may appear in winter, but the appearance of shoals occurs about mid-March, and after the May maximum the catch tails away, having furnished some 3½ million pounds of fish flesh in about six months. For the remaining six months a catch of about two million pounds from Mexico stocks the markets. The barracuda (*Sphyræna argentea*) belongs to a group of fishes represented in tropical waters throughout the world, but little has been known until now about their habits and life-histories. The importance of the American and Mexican fisheries, however, has led to a thorough investigation of the Californian species, and the results have recently appeared from the Division of Fish and Game of California as *Fish Bulletin No. 37* (1932), by Lionel A. Walford. The spawning period begins in April, reaches its climax in June and ends in September, and the number of eggs laid depends upon the size of the fish, a two-year old of 50 cm. length containing about 50,000 eggs, a seven-year old of 91 cm. about 340,000 eggs. The fish may attain an age of at least eleven years. An analysis of the catch-records in relation to fertility suggests that the present legal limit of three pounds should be replaced by a limit of not less than 30 in. length.

Summer Thermocline in Seas and Lakes

Solar radiation is absorbed by the surface waters in lakes and seas causing them to become warmer and lighter than the water beneath. In temperate climates, during a quiet summer, heating of the surface warm layer may continue and by August a difference of as much as 7° C. may be found between the surface and the twenty-five metre layers. There is often an abrupt transition between these warm and cold layers, often called the thermocline or discontinuity layer. This may occur at about twenty metres in the English Channel, first becoming evident usually in May, and at between forty and fifty metres in the Barents Sea. The thermocline may be broken down by a period of stormy weather resulting in a uniform distribution of temperature down to a considerable depth. Due to this mixing, in a shallow sea, sunless stormy weather may lead to high bottom temperatures, whereas in a sunny, quiet year with high surface temperature, the bottom temperatures will be low. Although often left out of consideration, this is probably a factor of importance in the distribution of animals and plants in different seasons.

Societies and Academies

London

Royal Society, May 18. W. T. Calman and Isabella Gordon : A dodecapodous pycnogonid. *Dodecolopoda mawsoni*, a new species representing a new genus of Pycnogonida, is described. It was obtained by Sir Douglas Mawson in the antarctic, and has the remarkable peculiarity of possessing six leg-bearing somites. It is suggested that the ten-legged and twelve-legged Pycnogonida originated by the development of instability in the metameric pattern of octopodous forms ; also that the Pycnogonida as a whole may owe their origin to an analogous disturbance of the cephalic metamerism of normal Arachnida (see also Nature, 131, 242, Feb. 18, 1933). J. Gray : Directional control of fish movements. In all the fish examined, a change in the direction of motion is effected by propagating an abnormally large wave of muscular contraction down the side of the body towards which the animal turns. During the first phase of the movement the anterior end of the fish turns on the posterior end, which remains relatively stationary in position. During the final phase of the movement the posterior end of the body moves towards the new axis of movement and during this process the anterior end of the animal remains relatively stationary. Except for fish with long and flexible bodies, the caudal fin plays an essential rôle during turning movements for it enables the posterior end of the body to act as a fulcrum on which the head is able to move through the water. A typical pelagic fish such as a whiting can turn through 180° within a circle the diameter of which is not greater than the length of the whole fish.

Paris

Academy of Sciences, April 10 (*C.R.*, **196**, 1057–1152). Jules Drach : The congruences of right lines and their focal surfaces. Charles Richet : An aerofilter for the purification of air. Remarks on a recent note on this subject by Gaston Meniér and recalling an apparatus described in 1909 achieving the same object. Serge Bernstein : The Fokker-Planck differential equation. M. Gignoux and L. Moret : The internal structural units of the Alpine chain between the Pelvoux and Durance. J. Mirguet : Certain ensembles of right lines. Paul Mentré : A projective deformation of tetrahedral complexes. Antoine Appert : Orders of separability in abstract spaces. D. van Dantzig : Monobolic groups and nearly periodic functions. Juan Carlos Vignaux : The method of summation of Edouard Le Roy. E. Kogbetliantz : The approximate expression of the Laguerre polynomial $L_n^{(\alpha)}(x)$. Michel Luntz and Paul Schwarz : Coaxial annular alternate vortices and some phenomena of asymmetry relating to the rotation of a cylinder in a viscous fluid. Max Serruys : An optical manograph with small inertia. G. Lemaître : The formation of nebulæ in the universe in expansion. E. M. Antoniadi : Some changes recently observed on the planet Mars with the 83 cm. telescope of the Meudon Observatory. Léon Brillouin : How can supraconductivity be interpreted ? A. Pérard : The elimination of the error of parallax in precision thermometers. Lew Kowarski : The movement of liquid drops in growing crystals. Contribution to the study of the intermediate state between a crystal and its sublimed vapour. Henri Abraham : The laws of action at a distance in electricity. G. Allard : The calculation of electric moments. R. Forrer : Interatomic electrons in crystalline networks. A. Sesmat : A new form of Michelson's experiment. G. A. Boutry : A precision densitometer with a photoelectric cell. Pierre Auger and Gabriel Monod-Herzen : Collisions between neutrons and protons. Mme. Irène Curie and F. Joliot : Contribution to the study of the positive electron. Mlle. C. Chamié : The expansion of the atoms of radioactive recoil in air. Henri Muller : The lowering of the eutectic point in the case of a ternary eutectic. F. Bourion and E. Rouyer : The cryoscopic determination of the total hydration of the ions of potassium chloride. René Wolff : Electrochemical phenomena of the catalytic decomposition of hydrogen peroxide by platinum. J. Barlot : A new method of analysis of bituminous schists. The mineral matter is removed by treatment with hydrofluoric acid. A study of the bituminous schist from the Creveney basin leads the author to the conclusion that this is not an impregnated rock like petroliferous sands, but a mother rock, possibly the fundamental mother rock of petroleum. Mme. G. Allard : The refractometric determination of organic acids. Mlle. B. Gredy : The acetylene linkage. The study of some bisubstituted acetylene hydrocarbons. Details of the Raman spectra of eleven bisubstituted acetylenes : all show two lines of unequal intensity in the region 2200–2300 cm.$^{-1}$. Jean Amiel : The slow combustion of benzene. A mixture of the composition $C_6H_6 + 15O$ under an initial pressure of one atmosphere was heated at temperatures between 400° C. and 540° C. The experimental results are given graphically. J. A. Gautier : *N*–Hydroxyethyl–α–pyridone and some of its derivatives. F. Kayser : The two diastereoisomeric 1.2.3–triphenyl–1–propanols. The exclusive preparation of each of them starting with the oxides of stilbene and isostilbene. Charles Prévost : An iodo-silver-benzoic complex and its application to the oxidation of ethylene compounds into α-glycols. A solution of iodine in benzene reacts with silver benzoate giving a compound $(C_6H_5.CO_2)_2AgI$ which can be crystallised from hot benzene. This reacts with ethylene derivatives giving good yields of the corresponding glycol benzoates. J. Barthoux : Lapis lazuli and balas rubies of the Afghan cipolins. Mlle. E. David : The Oligocene and Burdigalian of northern Syria. P. Corbin and N. Oulianoff : The inclination of the granite sheets in the Mont Blanc massif. James Basset, Mme. E. Wollman, M. A. Machebœuf and M. Bardach : Studies on the biological effects of ultra-pressures. The action of very high pressures on bacteriophages and on an invisible virus (vaccine virus). The resistance to pressure of the bacteriophages is of the same order as that of vaccine virus and much less than that of the diastases and toxins previously studied. E. Roubaud : Desert anhydrobiosis and its influence on the animal cycle of *Schistocerca peregrina*. Preserved in air of low humidity, the winged locusts remain in an immature state and their normal manifestations of reproductive activity are retarded. Placed in moist air, sexual activity is recovered in a few days. H. Bordier : Merget's phenomenon may be produced by the vaporisation of solid bodies. Mme. Y. Khouvine : The synthesis of cellulose by *Acetobacter xylinum* starting from mannite and sorbite. Michel Polonovski, Paul Boulanger and Gaston Bizard :

Pancreatic ammoniophaneresis. A. Jellinek: Measurements of temperatures in the interior of an egg placed in the electric field of ultra-short waves.

ROME

Royal National Academy of the Lincei, Dec. 18. E. Almansi: Deformations of elastic strips (2). G. Ascoli: The conditions for the validity of Taylor's development in the real field. D. Bonvicini: Non-infinitesimal deformations. M. Kourensky: The integration of the equations to the partial derivatives of the second order with two functions of two independent variables (4). Systems containing three derivatives of the second order. G. Mammana: The numerical solution of a system of equations. Maria Pastori: Tensorial assemblages generated by Pascal-Vitali absolute systems. F. Zagar: The increase in mass of a planet by the effect of cosmic dust (1). Premises and a particular case. In Levi-Cività's treatment of this question, the translatory motion of the planet as a material point is considered. For the case in which only the surface elements are struck by the dust, while the internal points retain their mass unchanged, the general expressions are now deduced and a particular case is discussed. G. R. Levi and D. Ghiron: Magnesium chlorite and double chlorites of copper with magnesium, barium, and thallium. Magnesium chlorite, $Mg(ClO_2)_2$, $6H_2O$, obtained by double decomposition from concentrated solutions of barium chlorite and magnesium sulphate, followed by slow evaporation in the dark, forms pseudocubic, rhombohedric, colourless crystals having the density 1·62 and the axial ratio $c : a = 2{\cdot}45$. The following double chlorites have also been prepared: $2\,Cu\,(ClO_2)_2$, $Mg\,(ClO_2)_2$, $8H_2O$, in brown crystals appearing yellow in transmitted light; $Cu\,(ClO_2)_2$, $Ba\,(ClO_2)_2$, $4H_2O$, in yellow crystals showing green fluorescence; $Cu\,(ClO_2)_2$, $Tl\,ClO_2$, $2H_2O$, as a reddish-brown, crystalline powder. These double chlorites are markedly more stable than copper chlorite itself. A. Fabris: The absorptive power of soil for pyrophosphoric acid. It has been already found that pyrophosphates take part in the transformation cycle of phosphoric acid in the soil and in the phosphatic nutrition of plants. Experiments made with soils of different characters show that these are capable of fixing the pyrophosphoric ion from solutions of pyrophosphates. This absorptive power is shown in greatest degree by the organic constituents of the soil. Under the experimental conditions employed, the absorption from $0{\cdot}1\,N$ solutions reaches its maximum intensity in about twenty-four hours, whereas with more dilute solutions ($0{\cdot}01\,N$) the maximum occurs after a few minutes. The phenomenon exhibits the characters of a typical colloidal absorption effect. T. Carpanese: The mineral deposits of Monte Rosso di Verra (Monte Rosa group). As a conclusion to a series of investigations on the minerals occurring in these deposits, the results of a study of the rocks and of the mineralogical paragenesis of the deposits are given. F. Rodolico: The water in the tremolites of Monte Spinosa in the Campigliese. Debye-Scherrer photograms of Monte Spinosa tremolite, before and after dehydration, are not superposable and show marked differences in both the position and the intensity of the interference lines. The results obtained up to the present indicate that the water in this mineral must be regarded as water of constitution.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 19, 1–207, Jan. 15, 1933)*. W. E. Castle and C. E. Keeler: (1) Blood group inheritance in the rabbit. Only two agglutinogens were found in the blood of rabbits and they are inherited as Mendelian dominants, probably different allelomorphs of the same autosomal gene. (2) Tests for linkage between the blood-group genes and other known genes of the rabbit. No linkage has been found with five of the eight known gene-bearing chromosomes. C. D. Darlington: The behaviour of interchange heterozygotes in *Œnothera*. A. Dorothy Bergner, S. Satina and A. F. Blakeslee: Prime types in *Datura*. 'Prime' types are races with modified chromosomes and they are useful for testing. A. F. Blakeslee, A. Dorothy Bergner and Amos G. Avery: Methods of synthesising pure-breeding types with predicted characters in the Jimson weed, *Datura stramonium*. 'Prime' types are used as a source of modified chromosomes. John W. Gowen and E. H. Gay: Eversporting as a function of the *Y*-chromosome in *Drosophila melanogaster*. Preston E. James: The higher crystalline plateau of south-eastern Brazil. Ernst Cloos: Structure of the "Ellicott City granite", Maryland. Lincoln Dryden: Xenohelix in the Maryland Miocene. The term 'Xenhelix' has been given by Mansfield to large corkscrew-like structures found in the St. Mary's formation of Maryland. Similar structures are also found in the Culvert formation. They appear to be animal borings made by soft-bodied forms, always associated with a definite unconformable surface. Arthur E. Kennelly: Conference of the Symbols, Units and Nomenclature (S.U.N.) Commission of the International Union of Pure and Applied Physics (I.P.U.) at Paris, in July, 1932, and its results. A historical outline of the C.G.S. units and an unofficial summary of the results of the above meeting. John F. Shepard: Higher processes in the behaviour of rats. Rats differed considerably in ability to learn a maze. T. H. Chang, R. W. Gerard and M. Shaffer: The *in vitro* respiration of nerve. The increased respiration of nerves in serum and delayed rise in oxygen consumption is due to bacteria. Robert Gesell and Carl Moyer: Observations on the nervous control of respiratory movements. Eugene U. Still: On the metabolism of the pancreas. Oxygen consumption and carbon dioxide contents of venous blood from the gland were measured. Rudolf Ruedemann: Palæozoic planktonic faunas of North America. A planktonic fauna corresponding with that of the present Sargasso Sea is found associated with graptolites in the typical graptolite shales. Its distribution suggests 'Sargasso seas' east and west of North America in the Palæozoic Atlantic and Pacific Oceans and, in consequence, the very early existence of these oceans. Henry Fairfield Osborn: Biological inductions from the evolution of the Proboscidea. The fundamental principle of evolution is germinal stability, adaptive biomechanical variation of the germ plasm being merely secular. The term aristogenesis is given to this germinally predetermined evolution always tending toward improvement. Recent palæontological work on proboscidean teeth gives further support to the hypothesis. A. Franklin Shull: The time of embryonic segregation in aphids as determined from intermediate types. The change from gamic to parthenogenetic individuals is marked by a definite series of changes; the direction of this series should give two complementary series. Three quarters of the intermediate types produced support the 'time of determination' hypothesis. G. H. Parker: The cellular transmission of neurohumoral substances in melanophore reactions. The denervated area on the tail of a chub shows very slow response to background changes. It is suggested that the cellular transmission this indicates is the primitive mode. William Beebe: Preliminary account of deep sea dives in the bathysphere with especial reference to one of 2,200 feet. The pressure and temperature outside the bathysphere were 993·7 lb. per sq. in. and 53° F.; the total pressure on the bathysphere was 5,120 tons. The eye could not detect any light below 1,700 ft. Fish and other organisms observed, many of them carrying their own illumination, were as active as surface animals and fish up to six feet in length were seen. It would seem that the usual trawling methods allow the larger and more active forms to escape. The dives have taken place off Nonsuch Island, Bermuda. Jesse Douglas and Philip Franklin: A step-polygon of a denumerable infinity of sides which bounds no finite area. Jesse Douglas: Crescent-shaped minimal surfaces. G. A. Miller: Groups generated by two operators of order 3 whose commutator is of order 2. J. L. Walsh: Interpolation and an analogue of the Laurent development.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Monday, May 29

University of London, at 5.30—(at University College, Gower Street, W.C.1).—Prof. W. K. Gregory: "The Evolution of Man from the Lower Vertebrates" (succeeding lectures on May 30 and June 1).*

Institute of Education, at 5.30.—S. Charléty: "L'Etudiant à Paris à travers les âges".*

Royal Geographical Society, at 8.30.—Major R. A. Bagnold (read by W. B. K. Shaw): "The South-West Libyan Desert".

Tuesday, May 30

Royal Society of Arts, at 4.30.—Dr. H. E. Hurst (Director-General, Physical Department, Ministry of Public Works, Egypt): "The Sudd Region".

London School of Hygiene and Tropical Medicine, at 5.—Dr. F. C. Shrubsall: "Mental Deficiency" (succeeding lecture on June 1).*

Royal Aeronautical Society, at 6.30—(in the Lecture Hall of the Royal Institution).—Col. F. P. Lahm: "Training of the Airplane Pilot" (Wilbur Wright Memorial Lecture).

Thursday, June 1

University of Oxford.—Prof. H. N. Russell: "The Composition of the Stars" (Halley Lecture).

Friday, June 2

London School of Hygiene and Tropical Medicine, at 2.—R. R. Hyde: "Industrial Welfare".*

Institution of Mechanical Engineers, May 30–June 2.—Summer Meeting at Edinburgh.

Royal Institute of Public Health, May 30–June 4.—Annual Congress at Eastbourne. The Right Hon. Viscount Leverhulme, president.

History in Science

SPEAKING at Oxford a few days ago in connexion with the celebration of the 250th anniversary of the Old Ashmolean, Sir Frederick Gowland Hopkins, president of the Royal Society, made a strong plea for increased attention to the history of science in secondary schools and universities in Great Britain. He suggested that

> "the history of science—the history of the gradual development of the fundamental ideas and conceptions, perhaps its effect upon civilisation—might form the subject of school teaching and take the place of the purely technical teaching of science which the schools at present give. That would turn out not only men who are going to take up science as a career, but the right sort of teaching would give that sympathy with and understanding of science which we would fain have in our public men and in our citizens generally."

Two main ideas seem to be expressed in Sir Frederick Hopkins' words—one that the usual science teaching in schools is too specialised for the educational equipment of the rank and file: the other, that historical aspects of scientific achievement and progress afford a suitable means of creating interest in them without technical details. Both propositions have been given much consideration in recent years, and the results are to be found in various reports as well as in modern textbooks, a number of which are now available providing courses of general or everyday science, while others, dealing with specific branches of science, devote much more attention to the historical side than was formerly done.

These developments are all to the good and represent a reaction against the type of school science which seemed to assume that every pupil was to become a chemist, physicist or engineer. For the rank and file of pupils in secondary schools, who will not in most cases proceed to scientific careers, something more is needed than laboratory training in scientific method, and it can be found in descriptive lessons and reading on everyday applications of scientific discovery, such as are exemplified in industrial history, on the establishment of great principles, and on many interesting aspects presented by the broad field of natural fact and phenomena.

On account of pressure of school examination requirements, there are practical difficulties in making the science course extensive as well as intensive, but a way to overcome them is indicated in a report on "The School Certificate Examination" which was the subject of an article in these columns of February 18 last. The recommendation made in this report was that every candidate who presents himself in science in the School Certificate examination should take an obligatory paper covering an extensive field, of a general scientific knowledge character, and should take, in addition, special papers on physics or chemistry or biology, but if these three papers are taken then the candidate can be excused the general science paper. It is greatly to be hoped that the university authorities responsible for the conduct of School Certificate examinations will give serious consideration to this scheme and will introduce syllabuses which will encourage its adoption in schools.

In a general science course of the kind contemplated, the history of science would, however, only be incidental. The main aim would be to encourage intelligent interest in the objects and manifestations of Nature and the endeavours of men of science to understand and use them. The place of history in the development of a particular branch of science is another matter. Precise knowledge of the subject itself is required to understand the significance of the steps by which particular discoveries have been reached, and such details are inappropriate to a general science course.

Fifteen years ago, when Sir. J. J. Thomson was president of the Royal Society, he presided over a Government committee which produced a valuable report on "The Position of Natural Science in the Educational System of Great Britain". Among the chief recommendations of that committee was one on the importance of increased attention to the history of science. It was suggested that such courses are particularly suitable for students not specialising in science, and that they should deal, not only with the history of specific branches of science of general interest, but also with the development of scientific ideas, the lives and work of scientific men, the bearing of scientific inventions on industrial progress, and the method and philosophy of science historically treated. Among the subjects which come appropriately under one or other of these heads are historical considerations of the development of views on the constitution of matter; the conservation of energy; the doctrine of evolution; methods of transport by land, water, and air; means of communication, such as telegraphy, telephones, broadcasting; methods of lighting; and the schools of thought represented by Aristotle, Archimedes, Galileo and Newton, as well as the work of Pasteur, Lister, Faraday, Darwin and Mendel and other experimental philosophers. Courses of this kind give special opportunities to teachers who combine some knowledge of history with a knowledge of science, and they appeal to students with historical tastes.

Many science teachers to-day realise the value of courses in which the humanising aspects of history and biography are combined with the practical study by which the meaning of experimental method is appreciated. It is, however, one thing to point out the stepping stones which have been the path of scientific progress in a particular subject and another to show the bearing of discoveries upon the advance of civilisation. To the student of chemistry the relative contributions of Priestley and Lavoisier to the discovery of oxygen and its bearing on the phlogiston theory are of interest and importance, but in human history the discovery itself is not so significant as the use of oxygen in medicine, aviation and the arts.

The history of science may, indeed, be approached from two points of view. It may be regarded purely as growth of knowledge of natural objects and phenomena along the corridors of time, or it may be viewed selectively according to its influence upon social and economic conditions. Hitherto these two provinces have been surveyed by different groups of students, and only occasionally have the qualities required for the effective description of both been possessed by a single worker. The result is that we have on one hand histories of astronomy, chemistry, biology, and other branches of natural science, none of which discusses the relation of the knowledge to social conditions or effects, and on the other hand histories of countries and periods giving scant attention to scientific genius and its influence upon human life and institutions.

What is wanted is a closer co-ordination of these separate points of view in works on general history. No one now supposes that a descriptive catalogue of kings and the intrigues of their courts and governments constitutes the history of a country. The determining factors in social development may be rulers or governments or peoples or scientific knowledge; and the power exerted by these respective influences decides the extent and character of the national or international changes effected. Just as, in mechanical science, work is not considered to be done until the point of application of the force is moved, so history is being made only when the power used produces an effect. Regarded in this way, science in the history of civilisation becomes a study of scientific causes and human consequences, and not a continuous chronological record of the growth of natural knowledge.

For the education of most young citizens, therefore, whom Sir Frederick Hopkins appears to have in mind, we suggest that what is wanted is not the history of science as such but of its social and industrial influences. "No one," said Comte, "can be really master of any science unless he studies its special history, which again is bound up, at every step, with the general history of humanity." We have often been reminded in recent years of these social and economic contacts; and it is upon them that the chief emphasis should be placed when attention to the history of science is being advocated for students in schools or universities.

Preservation of Wild Life in India

AN appeal made by the Association for the Preservation of Game in the United Provinces of India, in the first report of the Association recently issued (Agra: Hasan Manzil, Shahganj) shows the need for concentrated and swift action in its support. For long years this area of India has suffered heavily; in part from the toll of life taken by sportsmen, and in part by the natives under one pretext or another. It is not only the existence of the larger mammals which is threatened, but also of bird-life, especially of the ducks, which have been, and are being, destroyed by thousands either by shooting or by netting.

The existing close-season regulations are more honoured, we are told, in the breach than in the observance, while the issue of licences to all and sundry is reckless; and these include not merely ordinary firearms but quick-firing and magazine rifles. A plea is urged for a revision of the present system of licensing and an embargo on shooting from motor-cars, over water-holes and salt-licks, and between the hours of sunset and sunrise. It is proposed to reduce the abuses which now exist in licences for the protection of crops. Here, as in Africa and elsewhere, this need for 'protection' has again been advanced for commercial ends.

Having regard to the innumerable devices which exist in the United Provinces for the slaughter of game, there is no occasion for surprise at the note of alarm which has been sounded. In some areas which were once prolific, game has been absolutely wiped out. All good sportsmen, we feel sure, will deplore the state of affairs which now exists, and will join hands with those who are anxious to beat out the fires of destruction before they spread further, for there is still a remnant of a glorious heritage to be saved.

More than this; the members of this Association realise that they are the trustees for posterity. The present generation has no right to slay until the slaying stops for lack of victims. It is their duty to see that this does not happen; and this not so much in order that generations yet unborn may have something left to shoot, but that those who come after us may be able to make amends for our own abuse of the opportunities presented for the right use of this game.

Hitherto, game has been simply exploited, either to serve the ends of 'sport', or of commerce. Of the haunts and habits of these creatures, all that has come to light only suffices to guide those bent on killing to their prey. The tiger knows as much. What is needed is a concentrated study of the various types of game as they live their daily lives, unsuspecting the presence of man. Here we shall find the key to the problems presented by their evolution—what governs their choice of food, and its abundance, what governs their coloration, and their 'behaviour' in varying circumstances, their adjustments to their environment, and a hundred other similar problems.

These aspects in the life-history of game-animals never entered the heads of the older sportsmen: they are beyond the ken of the native *shikaree*. But they will be of vital importance to those who come after us; and we have no right to deprive them of their birthright, merely to satisfy the thirst for securing records, and 'trophies'.

The United Provinces, and the world at large, owe a debt which cannot easily be repaid, to His Excellency the Governor, Sir William Malcolm Hailey, the patron of the Association, and to its founders, the joint honorary secretaries, Major J. Corbett and Mr. Hasan Abid Jafry, who are sparing no efforts not merely to secure the necessary legislation, but also, what is quite as important, to spread a knowledge of the wild-life of India among the rising generation, by propaganda work. The Association seems at present to be the only one of its kind in India, but as conditions in the United Provinces apply also to many other parts of the country, it may be hoped that similar organisations for the preservation of game will be established.

Evolution Up to Date

The Mechanism of Creative Evolution. By Dr. C. C. Hurst. Pp. xi+365. (Cambridge: At the University Press, 1932.) 21*s.* net.

BY reasoning and reasonable men, evolution is now generally accepted as an article of faith. For though it cannot be proved in the sense of a mathematical proposition, the circumstantial evidence in its favour is overwhelmingly strong. When, however, we come to inquire into the manner in which it has come about, we are at once beset with difficulties. In the earlier days of evolution, and to some extent even to-day, these difficulties resulted merely in differences of opinion. For the doctors attempted to meet them by "argument about it and about", and the seeker after knowledge "evermore came out by that same door wherein he went". To-day this is all changed: or should be. Evolution may still be an article of faith, but heredity and variation, the so-called 'principles' on which it rests, have long since become matters of definite experimental inquiry.

In the last edition of "The Origin", Darwin stated that "the laws governing inheritance are for the most part unknown", and at the same time freely confessed to "our ignorance of the cause of each particular variation". With the rise of genetics, heredity has become an exact science, even as chemistry or physics, and the worker can plan out his experiments, knowing that in the fullness of time he will obtain a definite answer to a definite problem. The study of variation, too, has made immense progress in the past few years. Definite variations have, in many cases, been tracked down to definite alterations in the chromosomal content of the cell, sometimes alterations of addition, sometimes of subtraction. Moreover, the geneticist, no longer content merely to analyse what Nature offers, is producing variation by artificial means. Just as bombardment by X- and other rays is used by the physicist to analyse the constitution of the atom, so in a milder manner is such bombardment now being used by the geneticist to analyse the constitution of the chromosome and of the gene.

All this fresh influx of knowledge concerning the processes of heredity and variation must of necessity affect profoundly our conception of the manner in which evolution has come about. New and stimulating facts have been flowing in so rapidly that no worker yet appears to have had either the leisure or the inclination to set them out in a manner which can be readily comprehended by the general reader.

This gap Dr. Hurst has essayed to fill in the volume before us. It is a volume that should make an instant appeal to all who wish to know what is going on in one of the most rapidly progressing and exciting lines of present-day biological research. It is written with a lucidity that should render it easy reading even to those whose knowledge of this branch of science is relatively small. The author has reduced his use of technical terms to a minimum, and even where they cannot be avoided, their use should present no difficulty to the uninstructed reader of ordinary intelligence.

The aim of the book is to explain how the problems of evolution appear through the new genetical spectacles. It starts with a brief account of the nature of Mendel's discovery, and of the manner in which the facts of the geneticist fit in with those of the cytologist, showing that our conception of the constitution of the living creature is largely to be expressed in terms of the chromosomes and their contained genes, which are included in its living cells.

The bearing of all this on the nature of species is more clearly realised when the author comes to a discussion of hybridisation and polyploidy, a subject on which he is an admitted expert. Experimental mutation provides an attractive chapter, as also do the somewhat speculative ones on the nature of the gene and its relations to the smallest living organisms such as the viruses and the bacteriophages.

Taking it altogether, Dr. Hurst may be congratulated on an adequate and clear, semi-popular account of a subject advancing so rapidly that to treat of it in this manner is a matter of no little difficulty. If the book obtains its deserts, a new edition should be called for at no distant date, and for that reason we may direct attention to a few minor defects. Some of the figures, for example, Figs. 42 and 47, could well do with a little more explanation. The phenomenon of 'translocation' (p. 68) would be rendered clearer if illustrated with a good diagram. 'Deficiency', though illustrated by a diagram (Fig. 52), would be clearer for a rather fuller account in the text. Though Harrison's account of the appearance of melanic *Selenia* on treatment with certain chemicals is referred to and illustrated, no mention is made of McKenny Hughes's more recent failure to confirm that account. There are a few obvious misprints, for example, *Rhœa* for *Rhœo* (p. 78 and index), *Solensbia* for *Solenobia* (p. 259), *cerviciœ* for *cerevisiœ* (p. 274), *Collozoun* for *Collozoum* (p. 301). These, however, are minor blemishes in a book that is admirably printed and sumptuously illustrated. Though it may be rather on the expensive side, the purchaser can be assured that he will be obtaining a really beautifully produced book for his money.

Talking Pictures and Picture Telegraphy

(1) *Handbuch der Bildtelegraphie und des Fernsehens: Grundlagen, Entwicklungsziele und Grenzen der elektrischen Bildfernübertragung.* Bearbeitet und herausgegeben von Prof. Dr. Fritz Schröter. Pp. xvi + 487. (Berlin: Julius Springer, 1932.) 58 gold marks.

(2) *Tonfilm: Aufnahme und Wiedergabe nach dem Klangfilm-Verfahren.* (System Klangfilm-Tobis.) Herausgegeben für die Klangfilm G.m.b.H., Berlin, von Dr. F. Fischer und Dr. H. Lichte. Pp. xi + 455. (Leipzig: S. Hirzel, 1931.) 27 gold marks.

(3) *Einführung in die Tonphotographie: photographische Grundlagen der Lichtton-Aufzeichnung.* Von Prof. Dr. John Eggert und Dr. Richard Schmidt. Pp. vi + 137. (Leipzig: S. Hirzel, 1932.) 7 gold marks.

(1) PROF. SCHRÖTER and the authoritative collaborators whom he has gathered round him for this important book have done a great service to the study of the scientific and technical foundations of picture telegraphy and television. This is no mere compilation from the scattered literature of these two aspects of a single problem; it is a well-knit collection of original discussions, by recognised experts of wide experience, of the fundamental physics of the subject and of the practical engineering progress achieved. It clears television of much of the empiricism and wrong thinking which has characterised the somewhat unhappy history of that most attractive of subjects; it might have been modelled on the best interpretation of the startling but, within the implied limits, perfectly fair sentence which Prof. Karolus uses in his introductory note to the book, "Es gibt nichts Wunderbares".

The eleven chapters of the book deal in turn with: the methods of image dissection in phototelegraphy; the methods of image dissection in television (telecinematography); laws, problems, and limitations of scanning; photoelectric cells; picture recording and light modulation; synchronisation of picture telegraph apparatus; the picture amplifier; wireless picture transmission; wireless picture reception; picture transmission by line; and the forms and applications of the apparatus. There is a short but useful appendix of photometric and optical data, a specially convenient name index, and an adequate subject index. In a work in which all is well done, it is perhaps invidious to select items for special mention, but Prof. Schröter's own chapters on scanning or image dissection (chaps. i and iii), seem specially valuable because of their philosophical balance.

The specimens of transmitted pictures might lead a cynical critic to ask why those mountains of scientific knowledge and technical ingenuity are made to bring forth these mice, but such an inquiry would lead beyond the bounds of technology, possibly into entanglements with technocracy, without the promise of intellectual or æsthetic satisfaction in the end. One is convinced that the picture-telegraph engineer is much less interested in the fashion-plate or finger-print he sends across continent and ocean than in the joy of sending; that the æsthetic pleasure is in the process and not in the picture.

The book is produced in the best traditions of German scientific publishing, and its somewhat high cost in sterling is fully justified by its intrinsic merit.

(2) This description of the Klangfilm-Tobis system of sound-film working, edited by members of the staffs of the Siemens-Halske concern and of the Allgemeine Elektrizitäts Gesellschaft, has much in common with the book noticed above. Both books deal essentially with alternating current technique over a wide frequency range, and both find common ground in electro-optics. Within its narrower limits of subject matter, this book has the same width of scientific outlook, the same determined attack on fundamentals before technical tricks are discussed, and the same success in bringing together practically all the material required for a full understanding of the system. Drs. Fischer and Lichte have fulfilled their aspiration towards "a comprehensive scientific work in which all questions of the modern sound-film development are treated".

The first 250 pages of the book are devoted to the physical principles of the Klangfilm system. This section opens with short discussions on the Kerr cell, the oscillograph, the optical systems for the variable density and the variable area methods, the selenium cell, the photo-cell, the wax-disc recorder and the pick-up. Then follow chapters on the photographic principles of the variable density method, on microphones and loud speakers, amplification with special reference to tone correction, linear and non-linear distortion conditioned by the photographic process and by the apparatus, and the audibility of non-linear distortions. Adequate references by footnote and by bibliography are attached to the individual chapters.

The second half of the book contains a very full and very fully illustrated description of the individual parts of the complete Klangfilm apparatus, and ends with a short chapter on architectural acoustics and a description of the Neu-Babelsberg sound-film studios of the Ufa concern.

The copiousness of the pictorial aids to exposition is shown by the fact that the 450 pages of the text contain 378 illustrations.

(3) Prof. Eggert and Dr. Schmidt, writing from the scientific central laboratory of the photographic section of the I.G. concern, "Agfa", write in the tradition of the two works already noticed; their acknowledgments to Dr. Lichte underline the complementary relationship between this work and that of Fischer and Lichte. The book is devoted to a careful study of the part which the photographic processes play in the ultimate fidelity of reproduction from the sound-film. In the first fifty pages the authors summarise briefly but adequately the acoustic and mechanical foundations of sound-film technique; in the next fifty pages they deal with the photographic principles and processes.

The authors discuss the important differences among the characteristics of photographic response to weak illumination for several seconds, as in sensitometry, to moderate illumination for substantial fractions of a second, as in ordinary 'instantaneous' and cinematograph exposures, and to strong illumination with exposures of the order of 30 microseconds only as in sound-film photography, and show that the relative response as between the first and third cases is independent of the time of development, in a given developer. The resulting 'ultra-short-time' factor and the factor relating response to the diffuse light of sensitometry with the different response to the nearly parallel light of the sound-film processes are important in the practical control of these processes. The next section of the book deals with the frequency response characteristics of film materials, while the last section discusses the special properties of the range of "Agfa" films available for sound-film work.

The book ends with a list of references in which it is significant that the specific references to German, American and British sources are as 32 to 15 to 1, while the general list of journals dealing with sound-film questions contains three German, three American, one French and no British publications.

All three books are to be recommended to those interested in the remarkable development of the new arts based on electro-optics and electro-acoustics, and also to any who require reassurance as to the sure scientific foundations on which these typical modern industries are built, and as to the scrupulously quantitative technical knowledge which is embodied in every detail of their working.

Scott's Own Expedition

A Very Gallant Gentleman. By L. C. Bernacchi. Pp. 240+8 plates. (London: Thornton Butterworth, Ltd., 1933.) 8*s.* 6*d.* net.

COMMDR. BERNACCHI is a suitable writer for the first biography of Capt. Oates because he himself sledged over the Ross Barrier in Antarctica where the Scott tragedy occurred. He was physicist on the first expedition that wintered in the southern continent; he was also physicist in the *Discovery*, and he has introduced a little natural science into the biography. The science is well 'sugar-coated', for the book is popular though well-written. It also raises the question of publicity, commonly confused with merit, in connexion with recent expeditions; some of the best work has been done by explorers who are averse to the limelight.

Two subjects are treated in the book: the short life of Oates, and Scott's last expedition; they were closely connected, but the expedition occupies more space than the biography, which is the ninth volume inspired by this expedition, in addition to other writings and a wonderful film. Such profuse publicity is not objectionable unless it misleads those who do not know the work of other explorers.

"A Very Gallant Gentleman" is one of the best of the nine volumes for the ordinary reader, because most of its predecessors were larger and because Commdr. Bernacchi is a powerful writer.

The scenes, as he depicts them, live before the reader as vividly as in a film, even though there is little that is new; and the story was worth telling for the seventh time. The style is virile, and the pages of the book are adorned with some fine phrases and passages. Aesthetes may find the colour-tones strong, though others should not complain. There are, however, pages of irrelevant, if interesting, matter such as the description of Byrd's expedition; and there are a few inaccuracies. The *Discovery* expedition was not Capt. Scott's; he was appointed to its command. Sixty-five miles is by no means a three days' journey with dogs; Rasmussen drove ninety-four miles in one day, and 41 miles with 185 dogs on another day. In 1912 he drove four sledges, with 53 dogs, 296 miles in six days to end a journey of 630 miles in 26 days. Dog transport should not be classed with fancy sledging as if the necessity for cutting down weights to the last ounce existed. The average height of the Barrier usually accepted is 150 feet, not 200 feet above sea level.

There is also some repetition; but the book is well able to bear these small defects, and it shows that Oates was a fine character, worthy of a biography. He was lame from a wound received in South Africa where, incidentally, he was not the only officer to earn the title 'No surrender'. This book should be read by every boy as an inspiration to high endeavour, and it is hoped that the day will never come when such heroism as it depicts will be forgotten. Most of the illustrations are Mr. Ponting's.

Growth of Space Chemistry

Stereochemie. Von Prof. Stefan Goldschmidt. (Hand- und Jahrbuch der chemischen Physik, herausgegeben von A. Eucken und K. L. Wolf, Band 4.) Pp. xiii+311. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1933.) 29 gold marks.

FOR a long period Alfred Werner's classical "Lehrbuch der Stereochemie" (1904) held undisputed sway as the standard work on this branch of science. With the passage of time, and more particularly during the last few years, the need has become manifest for a fresh and up-to-date treatment of a rapidly expanding field of science which now claims the interested attention of chemist and physicist alike. Accordingly, several books dealing with the subject of spatial chemistry have appeared lately in rapid succession. None of them can be held to be entirely satisfying.

A glance at the list of contents of Prof. Goldschmidt's volume conveys the impression that he has fully covered his extensive field. There are sections on the stereochemistry of carbon, nitrogen and other elements; optical rotatory power and chemical constitution; and spatial configuration and reaction-velocity; while Dr. R. Bloch contributes a concluding section on the relationships existing between stereochemistry and crystallography. It may be said at once that the major part of the book can be read with pleasure and profit, and that it constitutes a useful contribution to the literature of stereochemistry.

After undertaking a detailed examination, however, one is left with the impression that the book falls between the two stools of a students' textbook and a work of reference. Moreover, although some of the sections do not call for serious criticism, others are unbalanced and show signs of hurried and uncritical compilation: here, much unnecessary information has been included, and there, the account is flimsy. In general, also, scant justice has been done to the work of British stereochemists.

The weakest part of the book is the treatment of methods of optical resolution—a subject of primary importance in a treatise on stereochemistry. The description of the method of spontaneous separation contains no mention of Purdie's fundamental work on inoculation—in fact, Purdie's name does not appear in the book. The particularly interesting example of the *iso*hydrobenzoins also passes unnoticed: but for this, the author would probably have modified his earlier statement (p. 18) that "experimentell nicht sicher geklärt ist die Frage, ob die Spiegelbildlichkeit der Moleküle auch *stets* in der Asymmetrie der Kristalle zum Ausdruck kommt" (compare *J. Chem. Soc.*, 2307; 1929). Here, as is so often the case in recent publications on stereochemistry, the author reproduces an opinion or statement from an earlier work without revising it in the light of later research. McKenzie's activation of racemic acid with *l*-malic acid has no bearing upon the work with which the author associates it in this section.

The description of Pasteur's second method of optical resolution and its extensions is similarly lacking in essentials. Some of the optically active camphor acids are mentioned, it is true; but there is no direct indication of the enormously important part these fundamental stereochemical reagents have played in the development of this branch of science. Incidentally, the formation of partial racemates in this type of resolving process is much commoner than the author supposes; and he does not mention other difficulties, such as the frequent formation of solid solutions, and the great tendency towards racemisation when the asymmetric molecule contains fewer than three carbon atoms. The method of resolving *dl*-alcohols by direct esterification—probably the most effective of all—is not noticed.

Hydroxymethylenecamphor, a stereochemical reagent of outstanding interest and value, is not referred to in the book. The ordinary use of this substance as a resolving agent is well known; but perhaps the most striking example of an optical resolution achieved by the so-called dynamic modification of Pasteur's second method is that of *dl*-*ac*.-tetrahydroquinaldine with *l*-hydroxymethylenecamphor (1913). The reaction is almost instantaneous; the two diastereoisomeric products are formed in the approximate proportion of 3 : 2; and the excess of one of them is easily removed. This remarkable optical resolution has found no mention in any textbook of stereochemistry known to the reviewer.

The note—for it is little more—on the biochemical method of optical resolution is quite inadequate. Indeed, the biochemical aspects of stereochemistry receive surprisingly little attention in any section of the book, and this strange neglect extends even to the brilliant series of investigations conducted in this field during recent years by Neuberg. The statement that *Penicillium glaucum* destroys only the *d*-component of ammonium racemate is another example of failure to correct an earlier and inaccurate opinion.

In the account of spirane derivatives (p. 40) the omission of Pope and Whitworth's *spiro*-5, 5-dihydantoin (1930) is regrettable, as this substance is the most interesting optically active compound of the class. Reference should have been made also to diamino-*spiro*-*cyclo*heptane (1932), the optical resolution of which is more impressive than that of the related *spiro*-*cyclo*heptanedicarboxylic acid. A somewhat similar remark applies to the omission of the diphenylethylene oxides (1930) in a discussion of the diagnosis of *trans*-forms by optical resolution (p. 118). In a different field, some attention should have been devoted to the numerous interesting publications by McKenzie and his co-workers in the last few years on the retention of optical activity during the migration of groups in de-amination and dehydration processes directly affecting the sole final asymmetric carbon atom in the system. The name of Tiffeneau does not occur in the narrative at all; and there is no reference to the optically active benzoins, with their important bearing upon the preparation of glycols and upon racemisation. The treatment of racemisation, asymmetric synthesis, and the Walden inversion is inadequate and partly incorrect: for example, at least four inaccuracies occur in the allusions to asymmetric synthesis on page 29, and the reference on the following page to the work of Marckwald and McKenzie is unintelligible.

A failing which this book shares with other recent Continental publications on chemistry is the gross carelessness shown in quoting names of investigators. We meet in Prof. Goldschmidt's pages such metamorphosed colleagues as W. Markwald, M. Lowry, F. Armstrong, A. N. Champbell, W. Cloogh, M. St. Lesslie, S. Patterson, P. Jakobson, H. Pillips, M. Jaeger and W. S. Keutish; H. Pickard in the text reverts to R. H. Pickard in the footnote (p. 24); W. J. Pope and S. J. Peachey appear in their normal guise on p. 83, but reappear later in sundry disguises, such as J. Pope and St. J. Peachey and W. J. Pope and J. Peachy; sometimes only one author is quoted for a collaborative paper; O. Jones publishes in the "Pr. Cambridge Soc."; another investigator is made to disprove his own work after his decease (p. 167); and the present reviewer is resolved into a dual personality, both in text and index, owing apparently to his having undergone a Walden inversion, resulting in a change from the *R*- to the *L*-form!

Such mistakes, if sometimes trivial, are irritating and indefensible; moreover, they appear to pass from one book to another. Inaccuracies in such points are unworthy of a book of the kind under notice, and they are apt to undermine the confidence of the reader. As examples of more serious errors, the following may be noted: "β-phenylethylamine" appears for "α-phenylethylamine" throughout the book; mandelic acid is not converted by nitrous acid into phenylaminoacetic acid (p. 94); no such compound as that indicated at the foot of p. 24 was described by Pasteur; and the alkaloids originally used by Pasteur in the optical resolution of racemic acid (1853) were cinchonicine and quinicine, and not cinchonine, as stated (p. 23).

The book is excellently produced, and the numerous diagrams are neat and effective. The index could be improved. The price, which at the present rate of exchange is about £2, is high.

JOHN READ.

Short Reviews

(1) *Logarithmetica Britannica: being a Standard Table of Logarithms to Twenty Decimal Places.* By Dr. Alexander John Thompson. Part 5: *Numbers 50,000 to 60,000.* (Tracts for Computers, No. 17.) Issued by the Biometric Laboratory, University of London, to commemorate the Tercentenary of Henry Briggs' publication of the *Arithmetica Logarithmica*, 1624. Pp. iv + 100. (Cambridge: At the University Press, 1931.) 15*s.* net.

(2) *Primes and Factors.* Computed by Emma Gifford. Pp. vi + 94. (Manchester: Printed by Abel Heywood and Son, Ltd., 1931.)

(3) *The Nomogram: the Theory and Practical Construction of Computation Charts.* By H. J. Allcock and J. Reginald Jones. (The Specialists' Series.) Pp. viii + 209. (London: Sir Isaac Pitman and Sons, Ltd., 1932.) 10*s.* 6*d.* net.

(1) PART 5 (the fourth to be published) contains the logarithms of the integers from 50,000 to 60,000. The frontispiece is a photographic reproduction of the title page of Briggs' "Arithmetica Logarithmica" (1624).

(2) Every prime number which is greater than 10 is included in the form $N = 6x \pm 1$. This volume gives all values of N from $x = 2$ to $x = 16{,}731$ together with the factors, if any. The table therefore contains all primes between 11 and 100,379. The terminal digits of each group of eight consecutive numbers are 1, 3, 7, 9, 3, 9, 1, 7 in this order. Each column of the table contains 56 numbers. With this arrangement, all numbers N in the same horizontal line have the same terminal digit. It is thus easy to find and factorise any number which falls within the limits of the table. The pages are well arranged and clearly printed. The volume should prove very useful.

(3) Alignment charts and other forms of nomogram are now widely used for rapidly obtaining approximate values of a number which is given by means of a formula containing several variables. The present volume combines successfully a study of the theory with practical directions for the construction and use of computation charts. The theory is based upon the determinant, the evanescence of which expresses the condition of collinearity of three points. The method is easily apprehended and readily applied. L. M. M.-T.

My Life and Thought: an Autobiography. By Albert Schweitzer. Translated by C. T. Campion. Pp. 288 + 8 plates. (London: George Allen and Unwin, Ltd., 1933.) 10*s.* 6*d.* net.

THIS book makes large demands on the reader, who is left to discover for himself the real eminence of Schweitzer alike as preacher or theologian, as musician, as doctor and as philosopher. In spite of the wealth of material for a romantic and heroic biography, there is little of the wide appeal of Schweitzer's narratives of his work in Lambaréné—"On the Edge of the Primæval Forest" and "More from the Primæval Forest". Apart altogether from the interest which any such attempt to face the fundamental problems of civilisation, to relate ethical and moral with material progress and values must possess, a rare and unmistakable honesty pervades the book which should give it added interest to the scientific worker. Here is a man of fourfold eminence facing frankly some of the fundamental problems of this generation, and, in his exposition of philosophy, giving us the clue to the understanding of the preacher, the musician, the physician.

Schweitzer's consideration of the relations between civilisation and ethics and attempt to discover the causes of the world catastrophe in a false world view, or sense of values, is somewhat pessimistic and leads him to conclude that there is no natural order of life values which man can discover. He adopts in consequence the principle of reverence for life as the only guide, and attacks the spirit of the age for its disdain for thinking, for the discouragement given to the individual to arrive at his convictions by his own thinking. "Renunciation of thinking," he declares, "is a declaration of spiritual bankruptcy. Where there is no longer a conviction that men can get to know the truth by their own thinking, scepticism begins." He attributes the difficulties of the machine age to the absence of a world view capable of counteracting tendencies destructive of civilisation. A challenging note, an almost passionate effort for honesty and sincerity of thought, breaking through the pessimism of the thought, like the inspiration of the man's personality no less than of his achievements, relieves the sombreness of what is near to being a disappointing book. Schweitzer writes shrewdly on problems involved in the relations of the backward races of Africa and European civilisation and his sense of service and missionary outlook are never allowed to deflect his scientific observation or judgment. (1) *Ergebnisse der kosmischen Physik.* Herausgegeben von V. Conrad und L. Weickmann. Band 1. (Gerlands Beiträge zur Geophysik, Supplementband 1.) Pp. xi + 448. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1931.) 46 gold marks.

(2) *Atmospheric Electricity.* By Dr. B. F. J. Schonland. (Methuen's Monographs on Physical Subjects.) Pp. vii + 100. (London: Methuen and Co., Ltd., 1932.) 2*s.* 6*d.* net.

(3) *Die Aufrechterhaltung der elektrischen Ladung der Erde.* Von Prof. Dr. Egon Schweidler. (Probleme der kosmischen Physik, herausgegeben von Prof. Dr. Christian Jensen und Prof. Dr. Arnold Schwassmann, Band 15.) Pp. iv + 68. (Hamburg: Henri Grand, 1932.) 5 gold marks.

(1) THE title of the first of these books is somewhat misleading, its subject being geophysics, and having

only incidental connexions with extra-terrestrial phenomena. The book is a contribution of exceptional value to the compilation-literature of science. It opens with an admirably comprehensive and concise account (86 pages) of auroræ, by C. Størmer, which is beautifully illustrated. Then follow two articles on special aspects of the penetrating radiation, namely, the barometer effect and the absorption coefficient, by W. Kolhörster and L. Tuwim; an account of atmospheric ozone, by P. Götz, and of abnormal sound-propagation in the atmosphere, by P. Duckert; and articles on geodesy, by F. Hopfner, and upon waves in air, water, and on sand, by F. M. Exner. The book is well bound and well printed, but its high price is regrettable.

(2) and (3) The present undue costliness of books published in Germany is emphasised by the other two books here noticed; they deal with substantially the same subject, and with about equal authority. The English book, unlike the German one, is bound, and is printed on equally good paper; it is in slightly smaller type, but contains about 25 per cent more words than the other; its price, even apart from the depreciation of sterling, is about half that of the German book.

Schonland's book gives an admirable short review of the electrical phenomena of the lower atmosphere, up to 10–15 km., and includes a chapter on the penetrating radiation. Schweidler limits his account to one special (but central) problem of atmospheric electricity, the maintenance of the earth's charge; he is more diffuse than Schonland, and while the latter does not cover every topic discussed by Schweidler, his book is undoubtedly the better introduction to the subject.

Blackboard Coloured Diagrams: Biological Series. Rana temporaria (The Common Frog). 44 in. × 31 in. *Rana temporaria* (Skeleton). 44 in. × 31 in. *Rana temporaria* (Brain and Nervous System). 44 in. × 31 in. (London: Sidgwick and Jackson, Ltd., 1933.) Mounted on cloth, eyeletted, 10*s*. 6*d*. each.

THESE diagrams are printed upon a black background as if drawn upon a blackboard and the actual area covered by the illustrations is 40 in. × 29 in. on each sheet. No names or key letters are provided and this is in some ways an advantage since it allows the instructor to give as many or as few technical names as may be thought desirable and enables them to be used for questioning. From their size they are adapted for use with small classes, say up to 50 but not to large lecture theatres accommodating 200–300 students. Even then, some of the smaller drawings, as, for example, the end-on view of the atlas vertebra and the diagram of the relationship of the dorsal and ventral nerve roots to the skin and a piece of muscle, are so small that they could only be seen properly in the front rows and would need to be examined at closer range by the students.

The diagrams are not all of the same standard. That of the skeleton is the best and reaches a high standard. The general illustration of the viscera is not quite so good nor is that of the nervous system, even allowing for the fact that they are not such satisfactory subjects for treating in this manner as a skeleton. In the former, some of the viscera are rather 'wooden' in appearance, for example, the fat bodies, and in the latter the general drawing of the nervous system is much like that of Ecker, which is very diagrammatic and exhibits an arrangement of the sympathetic nerves unlike that seen in ordinary dissection. Apart from these relatively minor points, the diagrams are well drawn and executed and should prove useful in schools and institutions where the classes are not large.

Reports of the Progress of Applied Chemistry. Vol. 17, 1932. Pp. 728. (London: Society of Chemical Industry, 1933.) 12*s*. 6*d*.; to Members, 7*s*. 6*d*.

THE volume of reports on the progress of applied chemistry during 1932 has appeared with customary promptitude and again reaches a high standard. This annual publication is one which few progressive chemists neglect to study. Many regard it as among the most useful books in their own libraries, and none can afford to ignore it. Moreover, dealing as it does with the general outline of progress in the various chemical industries and of industries in which chemistry enters as an aid to control and development, as well as describing very many of the more important technicalities underlying present and future progress, it appeals to the interest of the non-technical man who desires to keep *au fait* with the march of events in extremely important branches of the world's work.

The reports are presented in familiar form, are fully annotated with references to original papers and summaries to be found in "British Chemical Abstracts", and are provided with name and subject indexes. The report on explosives covers the years 1931 and 1932, and that which formerly dealt with fibres, textiles, cellulose and paper has been expanded into two separate reports. A. A. E.

Wanderers Wetterbuch: Einführung in das Verständnis der Wettervorgänge. Von Dr. Otto Myrbach. Pp. vi + 184. (Leipzig: Verlag Berg und Buch, n.d.) n.p.

To anyone with a love of Nature and a moderate knowledge of German, this book should make a definite appeal. The reader is introduced step by step to the elements of weather, the movements of air masses, clouds, rain and fine weather. Official forecasts and their application to local conditions are explained and this chapter is supplemented by one on local weather signs, but the largest and most interesting part of the book deals with weather in the mountains, ending with a four-act drama of a storm on the Zugspitze.

Forest Fires in Relation to Soil Fertility

By PROF. F. P. WORLEY, Auckland University College, New Zealand

WHEN the early colonists arrived in New Zealand, the greater part of the present cultivated land of the North Island and much of that of the South Island were covered with dense forests, which have since been removed by burning, the general practice being to remove millable timber, fell the remainder, burn out as completely as possible and sow with grass. Much of the forest was, however, burned without felling, sometimes by accident but often intentionally.

Although large areas of native forest still remain, the bush in the South Island is largely confined to mountainous regions. In the North Island, although the greater part of the remaining bush is on mountain ranges, there is still a large area of bush land that will gradually be brought into cultivation. The method of forest removal is not far removed from the primitive methods employed by some African native tribes.

Although it may be conceded that burning is the only practicable method of bringing bush land into cultivation, far too little consideration appears to have been given to the influence of forests on soil fertility and to the possible damage to the soil by the methods of burning employed. It is very obvious in numerous cases that areas formerly covered by luxuriant bush frequently have surprisingly low fertility. It has only to be recalled that the poor 'gum lands' of the North Auckland peninsula were once covered by dense kauri forests full of rich undergrowth. In other parts of the country, hillsides formerly covered by good bush, such, for example, as the coastal districts north of Wellington, have a fertility sadly below that to be expected from the luxuriance of the former bush.

It is necessary to inquire whether this apparent deterioration of fertility may be due to the method of forest removal and, for this purpose, consideration must be given to certain aspects of the part played by the forest in bringing virgin rocky land into a condition of fertility. The process can be observed on the volcanic island of Rangitoto at Auckland, where a formerly barren island of rough basalt is in process of being converted by the bush into rich, fertile land. It is not known how many hundreds of years it has taken for the island to reach its present degree of fertility, or how long it will be before the rocks are covered with fertile soil, but the process of humus formation is plainly obvious. What is not obvious, however, is the process of bringing to the surface and making available for plant growth the mineral constituents of the rocks.

The only artificial fertilisers intentionally applied to the land for agricultural purposes, apart from lime, are those supplying potassium, phosphorus and nitrogen. It is now recognised, however, that most of the other common elements occur in plants, though generally only in minute amounts, and that some of these minor constituents are essential to plants and to animals. Some may be present only fortuitously, but it is impossible to deny that they may have specific functions. Manganese and copper, for example, have been found in all plants investigated and are associated with rapidly growing parts, such as buds and leaves, and probably have a functional importance.

The small amounts of such elements in the soil are extracted by the roots of trees and transported to the growing parts, being eventually shed in the falling leaves, thus enriching the surface soil. This enrichment of the surface soil at the expense of the deeper soil by trees was clearly shown in the case of manganese by Bishop[1], and further investigations of a similar nature are desirable. Maquenne and Demoussy[2] examined the distribution of copper in a number of cultivated trees and shrubs and found the copper concentrated in the actively growing parts. Analyses of various parts of the native karaka tree have shown that the copper is concentrated in the leaves and seeds of this tree, and the same will probably be found in the case of other native trees. Copper is present normally only in minute amounts in the soil, but is gradually brought to the surface, like manganese, by tree growth. It is obvious that forests, besides building up a surface layer of humus, exercise the very important function of bringing to the surface various chemical elements extracted from the deeper soil. This process is cumulative and may extend over many hundreds of years.

In view of these considerations, it is possible to appreciate the damage that may be done by forest fires. Not infrequently the burning is sufficiently thorough to burn away the humus. On hilly ground the ash may be almost entirely washed away by rain, with the result that the beneficial cumulative work of the forest carried on over vast periods may be destroyed in a day. Unless the ash and the humus can be retained, the work of the forest has been not only in vain, but even actually detrimental, in that the soil to the depth of the tree roots will have been impoverished in minor mineral constituents essential to healthy growth of plants and animals.

On flat land the floor of the forest is usually damp. Here there is less likelihood of complete destruction of humus by fire and of ashes being washed away either mechanically or in solution, except on very porous soil, but on hill and mountain-side the destructive effects of bush fires may be disastrous.

The comparative infertility of the gum lands north of Auckland is probably due very largely to the destruction of the forests and the surface soil of the hills by great fires. In the low-lying and swampy gum lands a layer of ashes, covered often by many feet of black peat, overlies the remains of a kauri forest. Frequently, at a lower level there is another layer of ashes above the roots of a still earlier kauri forest. The prehistoric fires that destroyed these forests doubtless destroyed the forests on the hilly ground, where kauri gum occurs very near the surface. The humus on the sloping ground was apparently destroyed and the ashes washed down into the sea. In recent years the scrub has been burnt off by gum diggers and others and further damage done to the fertility of the soil.

On very porous soil the mineral constituents of ash derived from forest fires may be washed down through the soil. Should there be a tendency towards any mineral deficiency in such soil, this deficiency may be greatly intensified by leaching. On soil of this nature it would appear desirable to grow deep-rooting crops to bring to the surface the small amounts of essential minerals, and to produce a retentive layer of humus. Much working, with consequent drainage and leaching of the surface soil, should be avoided.

It appears probable that humus may have mineral as well as biological importance and more analyses are desirable of its mineral content, particularly for those elements that occur only in minute amounts in underlying soil or rock. It is obvious that if the normal soil and rock is in any way deficient in minor mineral constituents essential to the full health of plants or animals, this deficiency will become serious if the humus in which such constituents have become concentrated is destroyed and the ashes removed.

Canadian Water Power Development in 1932

By DR. BRYSSON CUNNINGHAM

THE strides by which Canada continues to advance in the exploitation of the water power resources of the Dominion for the generation of electricity are as remarkable as the abundance of the resources themselves. According to a report[1] recently issued by the Water Power and Hydrometric Bureau of the Department of the Interior, the total turbine installation at the end of 1932 amounted to more than seven millions (7,045,260) horse power, showing an increase of 378,923 horse power over the corresponding figure for the previous year. This gives an average of 670 horse power per 1,000 of population, a ratio which places Canada in an outstanding position among the water power-using countries of the world.

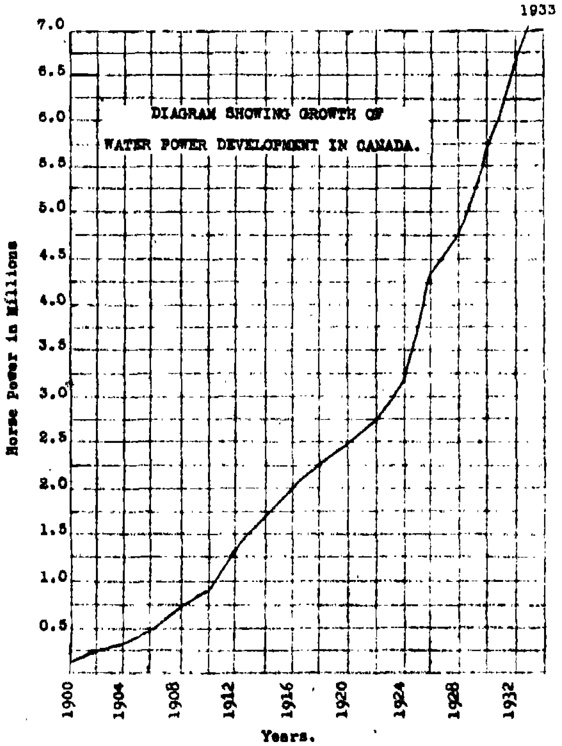

FIG. 1.

The remarkable character of the progress which has been made since the commencement of the present century will be best appreciated by a glance at the graph in Fig. 1, reproduced from the report. In 1900, the quantity of power realised was less than a quarter of a million horse power: it was still less than a million ten years later. By 1920, however, it had reached 2½ millions, and in 1930, 5¾ millions. Between 1928 and 1930, progress was at the rate of half a million horse power per annum, and practically the same rate prevailed up to the beginning of 1932. Last year, there was a slight falling off, but this does not necessarily imply any relaxation of effort, since the additional power is only recorded on completion of the particular undertaking from which it emanates, and anything from two to five years may be required for the execution of individual projects. Various schemes are at present under way, most of which had their inception three or four years ago, before the general suspension, or retardation, of industrial expansion, due to the world-wide financial depression set in. In common with the experience of nearly all countries, there has been of late years a definite decrease in the demand for power, which reached its greatest intensity in the middle of 1931. A recent statement[2] of the Minister of the Interior, the Hon. Thos. G. Murphy, gives, however, a hopeful impression. "More stable conditions," he says, "now appear to have been established, since the figures for the first ten months of 1932 indicate that electric energy produced for use in Canada is practically the same as for the corresponding period in 1931—an encouraging feature being that in August, September and October, the last three months for which statistics are available, an increase has been recorded."

The additional installations brought into operation during the last twelve months were located in five different provinces, but more than 97 per cent of the power was limited to three of them, and the largest of all the installations was made in the province of Quebec. The Beauharnois Light, Heat and Power Corp., Ltd., of Montreal, completed an initial instalment on the St. Lawrence River of 200,000 horse power (Fig. 2), forming part of a programme of half a million horse power designed to be realised in the course of the next few years, with a possible ultimate extension to two million horse power. This notable enterprise was begun in August 1929. It includes the construction of a canal (Fig. 3) about fifteen miles long into which is diverted about a quarter of the flow of the St. Lawrence, which averages some 220,000 cu. ft. per second. In addition to developing hydro-electric power, the new waterway, which is 3,000 feet wide, with a channel for shipping 600 ft. wide and 27 ft. deep, will complete the canalisation for deep-water navigation of all the wholly Canadian sections of the St. Lawrence, with the exception of a single reach round the Lachine Rapids at Montreal. The western entrance is on the southern bank of Lake St. Francis, a mile or two from the town of Valleyfield, whence it follows a wide curve until it enters Lake St. Louis near the town of Beauharnois, where the power house is situated. The fall at this point is 83 ft., representing the total difference in level between the two lakes. The power house contains accommodation for the reception of ten units of generating plant, each of a capacity of 50,000 horse power, and four of these machines are now in operation. Provision has been made for the extension of the building to a length of 3,000 ft., if and when it is called upon to take the entire flow of the river. The cost of the 500,000 horse power scheme has been estimated at a little less than 13 million pounds sterling.

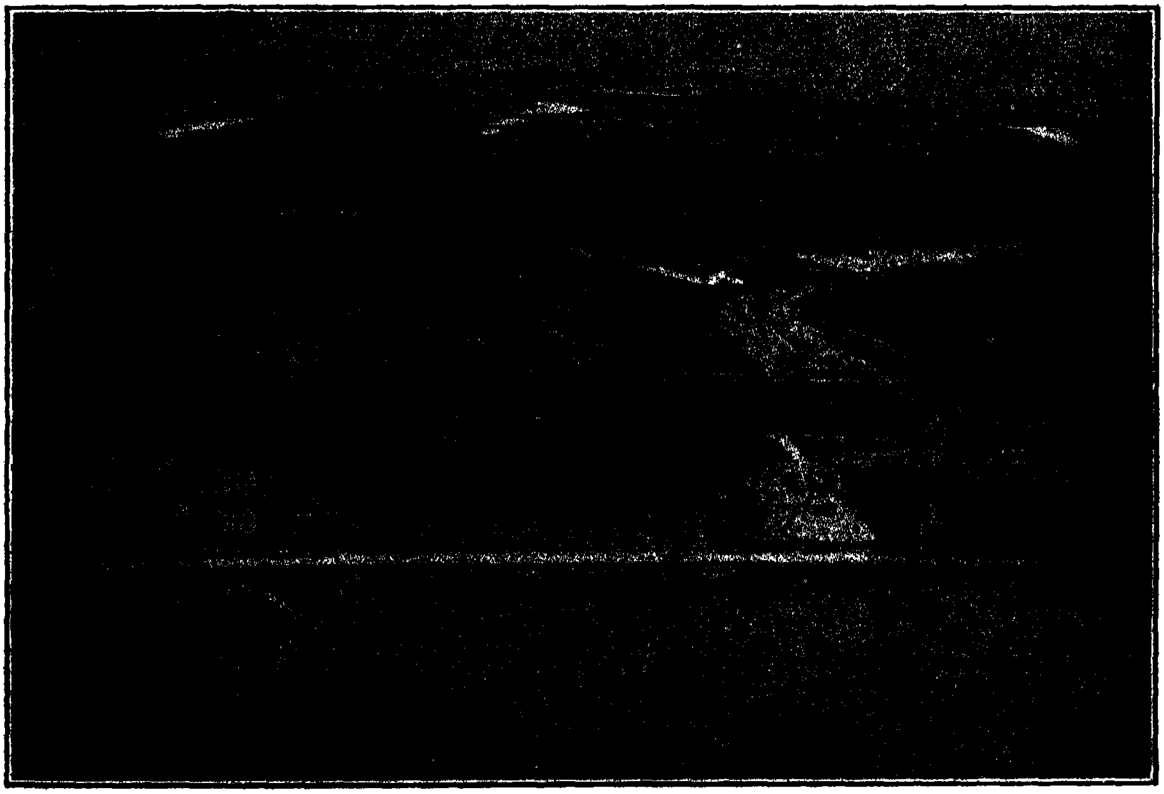

FIG. 2. Beauharnois Development, St. Lawrence River. By courtesy of the High Commissioner of Canada.

The foregoing particulars have been extracted, and the diagrammatic sketch map in Fig. 3 reproduced, by kind permission, from a brochure issued by the Beauharnois Light, Heat and Power Corp., Ltd., of Montreal.

Of the other two major installations, one of 56,000 horse power was the joint development of Chats Falls by the Ottawa Valley Power Co. Ltd., and the Hydro-Electric Power Commission of Ontario, and the second of 57,000 horse power at Corra Linn on the Kootenay River in British Columbia.

The accompanying table, which appears in the report under consideration, shows the available and developed water power in the whole of the Dominion, as recorded on January 1, 1933. The figures in columns 2 and 3 are minimum values, Available and Developed Water Power in Canada, January 1, 1933.

Province	Available 24-hour power at 80 per cent efficiency		Turbine Installation, H.P.
	At ordinary min. flow, H.P.	At ordinary six months flow, H.P.

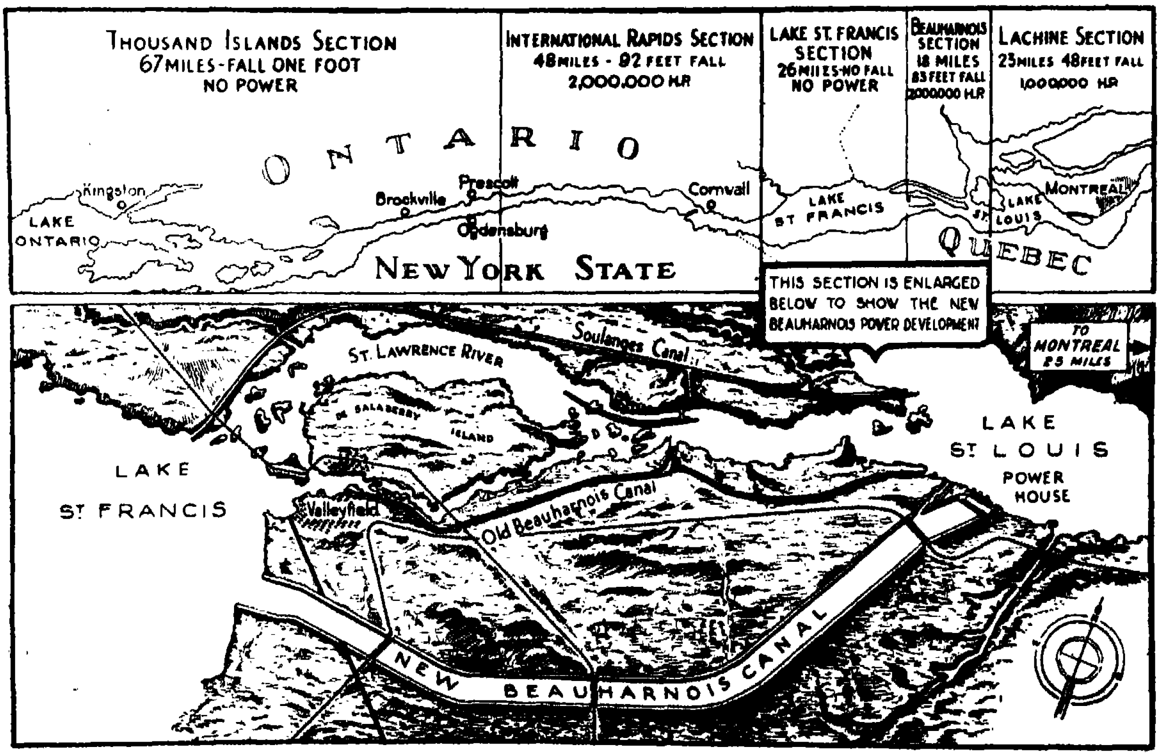

FIG. 3. Sketch map of Beauharnois hydro-electric power development.

and should be increased by 30 per cent if they are to correspond with the values obtained from actual installations. Accordingly, the total potential water power of the country may be reckoned at about 43,700,000 horse power.

It is of interest to form some idea of the economic value of these installations in saving of fuel. The coal equivalent of water horse power is not altogether easy to determine for lack of definite information about operating conditions of individual plants, but basing a comparison on fuel power elsewhere, a conservative estimate, under current conditions, indicates that, if operated continuously throughout the year, each installed horse power would effect a saving of approximately $5\frac{1}{18}$ tons of coal, so that the present aggregate installation of more than 7 millions horse power is capable of producing an economy of more than 35 million tons of coal per annum.

The actual saving in any year depends, of course, upon the actual kilowatt hour output of the plants during the year. Based upon the actual output of central electric stations, it is estimated in the report under consideration that the equivalent electrical production of the total water power installation in 1932 was approximately 18,300,000,000 kilowatt hours. Applying to this a moderate figure of 1·55 lb. of coal per kw.h. (based upon the average consumption of coal and coal equivalent per kw.h. during 1930 by all plants in the United States producing electricity for public use) there is indicated an actual saving for the year 1932 of more than twelve million tons of coal.

In view of the outstanding economic value of its water resources, it is not surprising that the capital invested in the various undertakings should exceed that invested in any other manufacturing industry of Canada. It is computed on a conservative basis that the aggregate amount of the capital involved is 1,620 million dollars or about £324,000,000 at par.

The scope for further development is, of course, considerable, and with so many examples of the remunerative value of this class of undertaking, progress bids fair to be continuous at a rapid rate for a number of years to come. Little more than 16 per cent of the total potential power is yet harnessed.

Geophysical Prospecting

IN prospecting for minerals, oils, water, etc., use can be made of the physical characteristics of the materials near the earth's surface. The methods at present adopted can be divided into four groups. The first group utilises the magnetic susceptibility of the materials, the second their density, the third their elasticity and the fourth group comprises various electric methods. The second group comprises the 'gravimetric' methods and the third the 'seismic'. In some cases two or more methods can be applied to the same area and so unwanted factors can be eliminated. The gravimetric method was made possible in 1888 when Baron von Eötvös published his work on the torsion balance. In 1914 Mintrop demonstrated experimentally the possibilities of the seismic methods. Prof. A. O. Rankine discussed the development of geophysical prospecting in his presidential address last year to Section A of the British Association at York.

In a paper read to the Institution of Electrical Engineers on April 7, J. M. Bruckshaw gave a detailed account of the electrical methods of surveying. As a rule, the interpretations of the electrical surveys are of a qualitative nature and in this respect they are not so good as the gravitational and seismic methods, which give indications of the depth and size of the material for which search is made.

There is now a tendency to develop more precise electrical methods with the object of placing them on a quantitative basis. The importance of making a preliminary geological survey and determining the resistivity of samples of the rock in the neighbourhood is now recognised. The results found in this way impose limitations on the use of the various methods that can be applied. If a known mass of ore occurs in the region under test, the interpretation of the results is greatly simplified by conducting the electrical survey directly over the known body.

As an example of the utility of geo-electrical prospecting, the case of a survey made by Mr. Broughton Edge in Cyprus was described. Mineralisation was suspected from the indications of old Roman activities in the neighbourhood. This led to the ground being examined by means of four adits and three shafts, but without result. Within three days of starting the electrical surveys, the centre was plainly indicated by the equipotential lines. The interpretation was confirmed by driving two adits and these encountered a large pyritic mass, the upper end of which lay immediately below the centre. Although the surface of the ground was very rough the equipotential curves on the map were smooth.

In survey work, rocks and minerals are divided into two classes, metallic conductors and electrolytic conductors. Practically all minerals showing metallic lustre are in the first class. In nearly all methods of electrical prospecting, an equipotential line method is first employed as this takes very little time and locates the most promising areas. These areas do not necessarily represent mineral deposits, for bands of clay and graphite-impregnated schists, etc., yield the same type of anomaly as an ore body. In some cases, geophysics may differentiate between a mineral deposit and a band of clay, but it is generally the geologist who determines which of the indications are caused by ore.

The depth to which the ground can be examined depends on the kind of method used. In the resistivity methods, the ground examined penetrates to a depth approximately equal to the distance between the electrodes. With great depths the results obtained are difficult to interpret. As a rule, it is not convenient to use currents greater than five amperes. Good results are sometimes obtained by using high-frequency alternating currents.

Obituary

PROF. VICTOR GOLDSCHMIDT

SCIENCE has to deplore the loss of another of her 'grand old men', Germany one of her most distinguished sons, and the world of culture at large one of the most accomplished, versatile and beneficent of its exponents, in the passing on May 8 of Prof. (Herr Geheimrath) Victor Goldschmidt, honorary professor of mineralogy and crystallography at the University of Heidelberg, at the ripe age of eighty years. His name has long been a household word with the small, but now happily increasing, coterie of workers in crystallography, which he was fond of calling the "Queen of Sciences"; and he was never tired of expressing his intense delight in the wonderful beauty of crystals. Yet so wide were his interests that in many other subjects he was almost equally distinguished, particularly ethnography, astronomy, physiology, colour in art, and tone and harmony in music. Having inherited great wealth—sadly depleted afterwards by the War—he was able to advance the interests of his subjects to an exceptional degree, and became a 'pious founder' in the truest sense of the term.

Born in Mainz on February 10, 1853, of Jewish stock, in the year 1871 he became a student of the Gewerbakademie of Berlin. Then from 1872 until 1878 he attended the celebrated Bergakademie of Freiberg, and during his last three years there acted as an assistant. In order to acquire further experience, however, he migrated in 1878 to the School of Mineralogy and Crystallography then growing up in Munich, which later became so famous under the guidance of Prof. von Groth; afterwards, in 1879, he went on to Heidelberg, where he took his degree of doctor of philosophy in 1880.

Prof. Goldschmidt had the inestimable advantage of the life-long help of a devoted and highly intellectual wife, a first cousin (formerly Fräulein von Portheim), who was both a remarkable linguist and keen appreciator of music and art in all its branches. Their home in Heidelberg, where they lived very simply and unostentatiously, but where they literally lavished hospitality and kindness on their many foreign visitors, was replete with valuable art treasures, such as Italian illuminated manuscripts, very early examples of printing, ancient French *objets d'art*, gems of every kind and a wonderful collection of crystals.

The laboratory of Prof. Goldschmidt at Heidelberg is a private one, which was provided and maintained at his own expense, but with the full concurrence of the University. He usually had working there, under his direction and that of his assistant Dr. Himmel, in mineralogy and crystallography, some ten to fifteen students, and also another half-dozen of more experience engaged in research, either for their doctorates or in a still more mature class of investigation. To this remarkable institution were attracted students possessing some previous experience from all over the world, including quite a number from England (especially Oxford and Cambridge) who were always warmly welcomed. Eventually in 1916 Prof. and Frau Goldschmidt definitely endowed the laboratory, together with an Institute for Folk-lore, and an ethnographical museum which they had also provided, as the "Josefine und Eduard von Portheim Stiftung für Wissenschaft und Kunst", in honour of their parents, Prof. Goldschmidt's mother and Frau Goldschmidt's father. Provision was also specially made for an English research bursary of about £150 per annum, to enable an English student of experience and promise but not too well provided with means to work with Prof. Goldschmidt, and incidentally to further friendship between Germany and England. On the eightieth birthday of Prof. Goldschmidt last February, the laboratory was formally named the Victor Goldschmidt Institut für Krystallforschung.

The published scientific papers of Prof. Goldschmidt form an immense list, numbering about 180, many of them masterpieces on specific minerals. Besides these papers he produced in the years 1914–26 the "Beiträge zur Krystallographie und Mineralogie", and since 1922 the "Heidelberger Akten der von Portheim Stiftung", and the "Materialen zur Naturphilosophie". Perhaps his most valuable contributions concerned blowpipe methods, which he carried to perfection, for the determination of minerals; crystal measurements by the theodolite method (azimuth and polar distance), using the two-circle goniometer which he perfected; and crystal drawing and calculation from the gnomonic projection, which he considerably elaborated. When we add to these his papers on etch- and solution-figures on crystal faces, his "Index der Krystallformen der Mineralien", his "Krystallographische Winkeltabelle", and last but not least his monumental "Atlas der Krystallformen" (1923) in nine volumes of figures and a like number of volumes of text, which took many years to complete, it will be obvious what a magnificent addition to our knowledge Prof. Goldschmidt has left behind him.

On the occasion of his seventy-fifth birthday Goldschmidt was presented with a "Festschrift", containing thirty-three original papers on mineralogy and crystallography, entirely contributed by his old students and a few personal friends; they included one from the late Dr. T. V. Barker of Oxford, and another by Dr. Mary Porter of the same University, who had received great kindness from Prof. Goldschmidt and his wife during the period of her work at his Heidelberg laboratory before the foundation of the bursary. It was published by the von Portheim Stiftung, under the editorship of Dr. Himmel, and with a foreword of appreciation of Prof. Goldschmidt's work by Prof. Milch. Prof. Goldschmidt was an honorary member of the Mineralogical Society in Great Britain, and of a dozen other scientific societies outside Germany.

Last December and January, Prof. and Frau Goldschmidt were in England, staying with the former's brother in London, and although when visiting the Master of Pembroke and Mrs. Hutchinson in Cambridge he appeared to be wonderfully vigorous, yet his relatives were then very anxious about his health. On leaving England they did not return home, but travelled to Salzburg in Austria, and before long it became necessary to remove from the hotel to a sanatorium, where Dr. Goldschmidt rapidly became worse, and where he died, as stated, on May 8. The recent happenings to his many Jewish friends in Germany cannot fail to have distressed him, and to have been a source of unhappiness during his last days. Yet he sought to find solace in planning further researches, and especially in compiling a review of the present position of crystallography, so as to discover the lines along which future research might most advantageously be prosecuted.

Unselfish to the end, Goldschmidt's thoughts were ever with the great institution which he had founded in Heidelberg, and now that he has been taken home and buried in that lovely spot by the banks of the Neckar, on the scene of his great life-work, we can only hope that the Stiftung and its traditions and especially the Victor Goldschmidt Institute for Crystal Research will be cherished as the worthiest memorial possible of this truly great man of science and perfect kindly gentleman. May his spirit inspire those who work there to emulate the master, and thus to produce further contributions of real value to our knowledge of the subject, the study of crystals, that was nearest his heart! A. E. H. TUTTON.

News and Views

Prof. Robert Chodat

THE recipient of this year's Linnean Medal awarded by the Linnean Society of London is Prof. Robert Chodat of Geneva. Unfortunately, he was unable to be present at the anniversary meeting held on May 24 and the medal was received on his behalf by the Swiss Minister. In the present state of specialisation, it is difficult to cover much of the field of botany and Prof. Chodat is one of the very few who can be considered a master in most branches. His work on the systematics of Polygalaceæ and their geographical distribution, and his ecological accounts of the vegetation of Paraguay explored by him in 1914 and of Portugal, Spain and Majorca which he visited with his students, are of great merit. In his laboratory at Geneva he elaborated the methods of obtaining pure cultures of Algæ now in general use, and his papers on Algæ, culminating in his monograph on polymorphism, have made him a recognised authority on the subject. More recently he has turned his attention to Fungi, particularly the organisms of fermentation, where his knowledge of chemistry and physiology has enabled him to make important advances. It is not so much the minutiæ of a subject as the broad principles that have attracted him, as is seen in his critical study of the palæozoic Pteropsida and in his address on the conception of species in modern botany. In genetics his contributions, though not numerous, have been fundamental. It is natural that he should be a successful teacher and his admirable "Principes de Botanique" reveal his wide and philosophic outlook. Geneva has always been famous for its botanists and Robert Chodat is a worthy successor to de Saussure and the de Candolles.

Prof. William A. Bone, F.R.S.

Prof. William A. Bone, of the Imperial College of Science and Technology, South Kensington, has been awarded the medal of the Society of Chemical Industry in recognition of his researches into the mechanism of combustion. This medal, which was instituted in 1896, is awarded periodically for conspicuous service rendered to applied chemistry, by research, discovery, invention or improvements in processes. It was in 1898, when Prof. Bone was lecturer in chemistry and metallurgy at Owens College, Manchester, that he started systematic research on the combustion of hydrocarbons and the influence of hot surfaces in promoting gaseous combustion, for which research he was elected a fellow of the Royal Society in 1905. In 1911 he was awarded the Howard Potts gold medal of the Franklin Institute of Philadelphia. In 1912 he began to organise and direct the new Department of Chemical Technology at the Imperial College, South Kensington. Prof. Bone's researches have comprised the chemical constitution of coal, surface combustion, gaseous combustion and explosions under high pressure, the photographic investigation of flame propagation during gaseous explosions, the combustion of hydrocarbons and blast furnace reactions. A lecture on July 12 entitled "Forty Years of Combustion Research" by Prof. Bone is one of the features of the annual meeting of the Society of Chemical Industry to be held in Newcastle on July 10–14.

Academic Assistance Council

THE present state of affairs in universities in Germany has raised in acute form the position of many scientific workers who, by reason of race, religion or political views, are unable to carry on their investigations in their own country. While no doubt universities in other countries will offer facilities to such displaced workers, it must be remembered that their resources are limited and in most cases already allotted. An Academic Assistance Council has therefore been formed in Great Britain, to co-operate with similar bodies in other countries in collecting funds to provide maintenance for displaced university teachers and investigators and in placing them in universities and institutions where they will be able to pursue their work. An appeal for funds, addressed to "all who are concerned for academic freedom and the security of learning", and signed by distinguished men of science and letters, has been issued, in which it is emphasised that the formation of the Council implies no reflection on political issues in other countries but is solely an attempt to relieve suffering, prevent waste of valuable talent and defend learning. The Royal Society has placed office accommodation at the disposal of the Council, and Sir William Beveridge and Prof. C. S. Gibson are acting as honorary secretaries. Communications and contributions should be sent to them at the Royal Society, Burlington House, London, W.1.

The Old Ashmolean, Oxford

THE celebrations, arranged by Dr. R. T. Gunther, of the two hundred and fiftieth anniversary of the opening of the Old Ashmolean on May 21, 1683, brought together a large gathering, which included representatives from a number of universities and scientific institutions in Great Britain and the United States. The Royal Society and the Linnean Society sent messages of congratulation, the latter referring particularly to the original specimens of the Tradescants forming part of the Lewis Evans collection. On May 21, a private reception was held in the Old Ashmolean building by Dr. R. T. Gunther. The guests took tea afterwards in Exeter College Hall, following the route taken by the Duke of York and his retinue in 1683, after the original opening of the Museum. On May 22, a private luncheon-party assembled in Wadham College Hall, and a toast in memory of Elias Ashmole was submitted. Sir Frederick Gowland Hopkins, who was among the guests, referred to the desirability of a fuller realisation of the value of historic science as an intellectual equipment and implement in current methods of education. In the course of the afternoon a lecture was delivered in the University Museum by Sir Arthur Smith Woodward on "Plot and Lhwyd and the Dawn of Geology". A survey was given of the position of natural science in Great Britain and in other European countries in the seventeenth century. The studies of Plot and Lhwyd were described. From the preface of the former to his work "The Natural History of Oxfordshire: an Essay towards the Natural History of England" (1677), it would appear that Plot was of vigorous temperament. He says: "But as for the hot-headed, half-witted Censurer, who, perhaps, only looks on the Title of a Chapter, or here and there a paragraph that makes for his turn, I must and do expect the lash of his tongue." The exhibition of objects of Ashmolean interest—especially those at the Bodleian Library in relation to Ashmole himself, and of great historic value—were a welcome form of dedication accompanying the celebrations.

The Neutron

THE Bakerian lecture of the Royal Society was delivered on May 25 by Dr. J. Chadwick, who took as his subject "The Neutron". Neutrons can be liberated by the bombardment of several light elements by α-particles, but, except from beryllium and boron, the yield of particles is very small. In some cases the experiments are consistent with the conservation of energy and momentum in the reactions. With beryllium, however, it is at first sight difficult to account for the whole of the energy available in the disintegration. From the data now available, the mass of the neutron is consistent with the view that the neutron is a complex particle formed by the union of a proton and an electron. Other arguments suggest that the neutron is an elementary particle. As an alternative, one might suppose the proton to be complex, consisting of a neutron and a positive electron, but this view also has certain difficulties. Dr. Chadwick dealt with experiments on the passage of neutrons through matter. Some interesting points appear in the collisions with the lighter nuclei, in particular with protons. In some cases inelastic collisions have been observed in which the atomic nucleus is disintegrated. When the radiation from beryllium, consisting of neutrons and γ-rays, passes through matter, positive electrons are occasionally produced. It is not yet known whether these are due to the action of the neutrons or to the γ-rays. The function of the neutron in the structure of atomic nuclei was also discussed.

Crested Rat at the London Zoo

THE authorities at the gardens of the Zoological Society have been fortunate in securing four specimens, from Kenya, of that most curious and rare rodent the 'crested rat' (*Lophiomys imhausi*); no specimen of this animal has ever before been exhibited in captivity, though it has long been known to science, having been described by Milne-Edwards so long ago as 1867. Though termed as 'rat', it has really no very close relationship to this animal. Indeed, owing to its many structural peculiarities it has been made to constitute a family by itself—the Lophiomidæ. Nor is it at all accurately described when it is said to be a "badger-like animal", for it bears no very close resemblance to any other known rodent. One of its most characteristic external features is the great crest of long coarse hair which surmounts the back, bordered on each side by two bands of white. The nature and function of a glandular tract running down from the nape tail-wards, along the back, has yet to be discovered. Until now, nothing was known of the young. But one of the new captives, since its arrival, has given birth, not to a litter, as one would have expected of a rodent, but to a single young one, and this has elicited a further fact new to science, since it was born with a coat of fur, and not naked as with other rodents. The fact that this animal is arboreal is not likely to have any connexion with this unusual condition of the new born young, and the fact that but one is produced at a birth.

Research in the Paint and Varnish Industries

ON May 25 the Research Association of British Paint, Colour and Varnish Manufacturers held an exhibition at its Research Station, Waldegrave Road, Teddington, Middlesex. The firms comprising the Association's members range from those concerned with the manufacture of linoleum to the manufacturers of printing inks and of polishes, the main body conforming in interests with the title of the Association. In the six years that the Association has been actively engaged in researches, this wide range of interests has necessarily given rise to a large number of apparently unrelated investigations. The industries concerned, however, all have to deal with the properties of fluids, of thin films, of pigments and with the inter-relations between the pigment and an embedding medium. The work on view on May 25 included new apparatus and technique for the measurement of the hiding power of pigments, of the gloss of surface films and of the tinting, fastness and bronzing characteristics of pigments, the rate of evaporation of volatile constituents from thin films, the reactions of detached films of paints, varnishes and lacquers to a steady load, a rapidly increasing load, and an alternating load. New methods of evaluating the technical utility of linseed, tung and other vegetable oils were on view, as well as small-scale manufacturing plant suited to the production of all types of varnishes, lacquers and paints. The very rapid recent advances in the field of synthetic resins were reflected in a series of chemical studies of the mechanism involved in the complex polymerisation processes on which the manufacture of these materials is based. In the field of pigment manufacture, several important advances in technique recently originated at the Research Station were on view. These concern improvements in dispersion of organic lakes, greatly increased resistance of lead chromes to photo-chemical and chemical influences and the treatment of prussian blues to overcome some of their usual defects from the point of view of dispersibility.

IN the afternoon, Dr. W. Krumbhaar, director of the corresponding German organisation, Institut für Lackforschung, Berlin, gave two interesting addresses on the subjects "No Illusions about Chlorinated Rubber" and "Commercial and Scientific Activities of the Paint Industry in England and Germany", to a large audience in the library at the Research Station. Among the many points of technical interest dealt with by Dr. Krumbhaar was his reference to the fact that, in Germany, a scientific man is regarded as having at least as much business acumen and ability as has his non-scientific confrère. It was evident from Dr. Krumbhaar's description of the activities of his own Institute that, in addition to carrying out a wide range of scientific investigation, a considerable amount of effort is expended in educating the German paint and varnish industry as to the details of various government restrictive orders and in protecting them from the evil effects of misuse of the patent system by large suppliers of their raw materials.

Leverhulme Research Fellowships

BY the will of the first Lord Leverhulme, who died in 1925, the income arising from a part of his estate is to be devoted to the provision of scholarships for "research and education". The trustees have now resolved to devote £12,000 a year to the establishment of a scheme of research fellowships. The fellowships are primarily intended to assist experienced research workers rather than workers in an early stage of their careers. The duration of the grant will normally not exceed two years. Fellows may work either at home or abroad and no subject of inquiry is excluded from the scope of the scheme. The advisory committee is constituted as follows: Dr. H. J. W. Hetherington (chairman), Prof. A. M. Carr-Saunders, Sir William Hardy, Dr. N. V. Sidgwick, and Mr. H. T. Tizard. Dr. L. Haden Guest has been appointed secretary. Applications (from British-born candidates normally resident in the United Kingdom) and all inquiries and communications in connexion with the scheme should be addressed to the Secretary, Leverhulme Fellowship Scheme, Union House, St. Martin's-le-Grand, London, E.C.1. It will be a convenience to the committee if as many applications as possible are in the hands of the secretary by June 19.

Recent Acquisitions of the British Museum (Natural History)

ACQUISITIONS for the Department of Zoology include a series of elephant skulls from the Gola Forest, Sierra Leone, the gift of His Excellency the Governor of Sierra Leone. These skulls are of great scientific value as they demonstrate the existence of a small race of elephant in West Africa. Dr. G. H. Rodman has presented a series of stereoscopic radiographs of Mollusca shells for exhibition. Among the donations to the Department of Geology is a large collection from Miss M. S. Johnston, mainly of Silurian fossils from England and Norway. A portion of a meteoric stone which fell on July 8, 1932, at Kahrapar, Jaunpur, United Provinces, India, has been presented to the Department of Minerals by Mr. H. Minson. A collection of Coleoptera belonging to the family Curculionidæ and numbering approximately 40,000 specimens, has been deposited in the Department of Entomology as a "permanent loan" by the Hawaiian Sugar-planters' Association of Honolulu. The collection, which is representative of the weevils of every part of the world, was brought together by the late Dr. David Sharp, after his first and largest collection of beetles had been acquired by the Museum in 1905. His British collection was acquired in 1932.

THE Department of Botany has had bequeathed to it the herbarium of Mr. James Groves, who was the recognised authority on Charophyta (stoneworts) and one of the best-known field botanists of Great Britain. He worked for many years in collaboration with his brother Henry, and together they edited the ninth edition of Babington's "Manual of British Botany". Henry died in 1912 and in 1918 a first consignment (6,000) of their British plants was presented to the Department. James later wrote the Ray Society's monograph on Charophyta with Canon Bullock Webster as joint author. The bequest includes more than 6,000 Charophyta and about 11,000 British flowering plants: the remainder are mosses and sea-weeds. All are well and carefully mounted ready to be incorporated in the herbarium. Dr. R. J. D. Graham, of the University of Edinburgh, has presented his collection of about 1,300 Mesopotamian plants made by himself and others. An account of the plants will appear shortly in "Notes from the Royal Botanic Garden, Edinburgh". The Sladen and Godman Trusts have presented about 900 plants recently collected on the Islands of the Gulf of Guinea by Mr. A. W. Exell, assistant keeper in the Department, in company with Mr. W. H. T. Tams, of the Department of Entomology. The islands visited were Fernando Po, Principe, São Thomé and Annobon, from which there was little material previously in the herbarium. The collections from Fernando Po were practically confined to the Inoka region in the south, a country with a most interesting vegetation unique in tropical Africa. There are many new records of plants and several new species. The collections will probably enable a general account of the geographical relationships of the four islands to be written.

Chemistry and the Art of Living

ON March 24 Prof. H. E. Armstrong delivered the Sir Jesse Boot Foundation lecture in the lecture theatre of University College, Nottingham. Recalling the fact that one of the most pleasant memories of his life was the hours spent under the roof of Sir Jesse and Lady Boot, he paid tribute to the quality that belonged to his late host and claimed that, in founding the chair of chemistry, Sir Jesse Boot did a service to his fellow citizens which will ultimately save them from themselves: providing they be taught the proper art of living, which will soon be the duty of chemistry. When this is achieved, "cash chemists" may cease to exist, as drugs are only used to counteract inborn faults in the human machine and insufficient food, deficiencies in food, effects of over-feeding or improper feeding, zymotic disease.

Hence the future lies with the farmer, who will have to produce not only the food that we desire but also that which we ought to have in a perfect condition. To do this, the farmer will have to feed his animals properly and this necessitates a great extension in the use of fertilisers on the land. Thus it appears that the "cash chemist" returns to action with a change of function—to supply the farmer with his chemical manures. Prof. Armstrong was despondent at the delay in reaching this condition of a brave new world and concluded with the following words: "at the moment our failure to use intelligence, the world over, is astounding—some fault there must be in developing it. A few months ago in a speech in this city I suggested clearing out the present race of students and their teachers and bringing in 500 chosen boys who could be trained as cooks. I would repeat my advice to-day but add that to cook should mean to understand what is cooked, what is fit and proper to be eaten, as well as the mere art of kitchenry. We cannot get away from the fact that we live always through our stomachs; from these it is, through the food we put into them, that we gain and have our being."

Electric Welding in Ship Construction

ELECTRIC welding, instead of rivetting, is being widely adopted in shipbuilding. In German naval dockyards it has practically superseded rivetting. Electrically welded ships have practically no leakage and there is little corrosion or wastage of plates around the welded joints. Economies are effected by welding in the weight and cost of a ship's hull. The welded ship therefore yields greater service for a smaller investment of capital. The University of Glasgow has introduced welding work into its laboratories and the design of welding joints has been introduced into all its engineering courses. The Glasgow Education Committee is also taking steps to form a new skilled class of workmen called ship welders. Before a change of this kind can be made it is necessary for the employers and the trade unions to meet. In the *Times* of May 26 an account is given of a conference held in Edinburgh between employers' federations and trade unions on this subject. Mr. J. B. Hutchison, the chairman of the employers, stated that it is of the greatest importance that the development of welding should proceed as rapidly and smoothly as possible in Great Britain on economical lines in order that competition with other shipbuilding nations may be successfully faced. It is understood that the employers made it clear that the selection of ship welders is likely to be made from the most suitable men, not confined to any one class and not necessarily from men directly displaced by the new process. Mr. Sherwood, on behalf of the unions, said that the proposals were of such a far-reaching character that full and careful consideration was necessary.

Electrical Equipment of the *Queen of Bermuda*

IN the G.E.C. (General Electric Co.) *Journal* for May there is a full and interesting description of the electrification of the Furness-Withy liner, *Queen of Bermuda*. It was launched at Barrow-in-Furness last February and has successfully completed its trials. Its tonnage is 22,500 and its shaft horse power is about 20,000. Electricity is used on the most extensive scale possible throughout the ship. It is used for the propulsion and steering of the ship. It is also used for lighting and ventilation, cooking, refrigeration, the handling of cargo, and there are eleven electric lifts, etc., the auxiliary machinery totalling about 3,000 horse power. For maintaining a supply of power adequate for essential services in cases of emergency, an oil-engine-driven dynamo of 50 kilowatts capacity is installed on one of the upper decks well above the water line. The change over of the panic-lighting circuits from the emergency busbars to a battery is entirely automatic and takes place on the failure of the supply voltage. The vessel is intended primarily for service between New York and Bermuda but she has been constructed for ocean-cruising as well. In view of the large amount of perishable foodstuffs which have to be carried, extensive refrigerating plant is provided. For this purpose, 23 motors are required, the largest being of 70 horse power for driving a carbon dioxide compressor. The lighting is done on a very lavish scale, requiring 450 kilowatts of electric energy. It is mainly effected by concealed lighting in opaque cornices, diffused lighting through continuous glazed cornices, or box lights glazed with tinted diffusing glasses in modern designs. For illuminating the dancing space three-colour lighting is used for the main ceiling. The lights are controlled by dimmers when dancing is in progress so as to produce a pleasing variation in the colour of the illumination. This is a great improvement on 'jazz' lighting.

Freshwater Biological Association

THE annual general meeting of the Freshwater Biological Association of the British Empire was held on May 11 in the rooms of the British Waterworks Association, Grand Buildings, Trafalgar Square, W.C.2. The following officers were elected for 1933–34:—*President*, Mr. Reginald Beddington; *Chairman of Council*, Prof. F. E. Fritsch; *Hon. Treasurer*, Mr. Nigel O. Walker; *Hon. Director of the Laboratory*, Dr. W. H. Pearsall; *Hon. Secretary*, Mr. J. T. Saunders. The report of the Council showed that considerable progress has been made in fitting out the Laboratory of the Association at Wray Castle at Windermere. Tables are now available for visiting research workers and accommodation for these workers is provided in the Castle. Subscriptions have been received from a wide circle interested in freshwater problems. Subscriptions, renting tables at the Laboratory, have also been received from universities, many of which have already nominated research workers to occupy their tables at the Laboratory. The Council is anxious to provide the fullest possible facilities at the Laboratory for those who wish to work on freshwater problems. The most pressing need at the moment is the provision of an electric supply for the Laboratory, but the Council has at present no funds to supply this need. The address of the honorary secretary of the Association is Mr. J. T. Saunders, Christ's College, Cambridge.

Australian Water Supply

THE water supplies of certain parts of Australia, and the occurrence of periodic drought, are the subject of comment by Dr. J. P. Thomson in an article in the *Sydney Morning Herald* of January 12. As a result of observations ranging over half a century, Dr. Thomson believes that there are unmistakable signs of desiccation and he advocates the immediate necessity of measures to preserve the water supplies and to resist the ill-effect of droughts. He points to observations on Lake George and various lagoons in the eastern part of New South Wales as well as Lake Eyre as showing rapid deterioration in humidity. The wells of the great artesian basin, according to him, are showing signs of decreased flow which he attributes to the plutonic and therefore limited supply of the water. He points also to the decreased flow in many water courses and the serious loss of water by excessive evaporation in the dry atmosphere. Dr. Thomson would like to see every effort to conserve water by preventing waste of flood water and checking the number of wells, and he favours also the preservation of fodder against times of stress. He points also to the urgent need of better weather forecasts, which he thinks must come from the antarctic, in order to give the farmer warning of any surplus or deficiency in rainfall. Measures such as these might go hand in hand with more land settlement and production for wider markets.

Russian Arctic Expeditions

IN recent years the Soviet Union has paid a great deal of attention to the exploration of its arctic territories and the investigation of commercial sea routes north of Siberia. The Society for Cultural Relations between the Peoples of the British Commonwealth and the U.S.S.R. has recently directed attention to the activities of Soviet arctic expeditions in 1932. Most important were the establishment of observatories at Cape Chelyuskin, at Rudolph Island in Franz Josef Land, in Novaya Zemlya and at the mouth of the Lena River. The Rudolph Island station is to be the base of a thorough exploration of Franz Josef Land and the little-known seas to the east. Several ice-breakers were engaged in hydrographical work in the Barents and Kara Seas while the *Sibiriak*, which made the north-east passage from Archangel to Bering Strait, reports that ice congestion in the western part of the passage can be avoided by passing north of Northern Land. It is by no means certain, however, that this route could be relied on every year in maintaining communication between White Sea ports and the Lena River, though the possibility is worth investigating.

Annales Guébhard-Séverine

WE have received No. 8 of these annals, which have been issued yearly since 1925 by the Institut Guébhard-Séverine, 4 Rue du Seyon, Neuchâtel, Switzerland, and are distributed free on application to the Institut, to investigators in all countries. The Institut is also willing to publish scientific works written in any of the languages French, English, German or Italian; its practice appears to be to translate into French for publication. Papers on subjects studied by the late Adrien Guébhard are particularly invited; these subjects include geophysics and geology, botany, electricity, hydrodynamics, osmosis, biological physics, meteorology, acoustics, photography and spectroscopy. The present number of the annals contains four papers, by R. Reinicke on the tetrahedral field of action of atoms, by F. Strunz on the natural sciences in the work of Albertus Magnus, by L. Courvoisier on researches to determine the 'absolute' motion of the earth, and by D. Chahnazaroff on petroliferous waters.

Institute of Physics

THE recently issued annual report for 1932 of the Board of the Institute of Physics shows a satisfactory record of work during the year. There has been a steady increase in membership of the Institute which now has about seven hundred names on its roll. The local sections, too, in Australia and India, report a successful year. During the year, a local section was formed at Manchester under the chairmanship of Prof. W. L. Bragg with Dr. H. Lowery of the Physics Department of the University as local secretary. The following officers among others have been elected for the session 1933–34: *President*, Sir Henry Lyons; *Treasurer*, Major C. E. S. Phillips; *Secretary*, Prof. J. A. Crowther.

Third International Congress of Experimental Cytology

THE third International Congress of Experimental Cytology will be held at Cambridge on August 21–26. The international president is Prof. Th. Huzella, professor of anatomy in the University of Debrecen, whose presidential address will be entitled "Culture des tissus en ses relations aux problèmes générales de la biologie et aux problèmes speciales de la médecine". The chief feature of the Congress will be discussions on the following topics: "Cell Respiration and Cell Metabolism"; "Cell Form and Function as demonstrated by Recent Advances in Tissue Culture"; "The Electro-Physiology of the Cell"; "Entwicklungsmechanik und Explantation"; "The Cultivation of Animal and Plant Viruses". Papers will be presented by authors from Great Britain, Germany, Austria, Hungary, U.S.S.R., United States, Poland, Italy, Holland, Czechoslovakia, France, Switzerland, Denmark, and Japan. Among the distinguished foreign visitors will be Prof. H. Wieland (Munich), Prof. A. Szent-Györgyi (Budapest), Prof. R. Chambers (New York), Prof. W. J. V. Osterhout (New York), Prof. J. Michaelis (New York), Prof. S. C. Brooks (Berkeley), and Dr. K. Landsteiner (New York). Further information concerning the Congress can be obtained from Dr. Honor B. Fell, Strangeways Research Laboratory, via Cherryhinton, Cambridge.

Twenty-fifth Anniversary of the French Society of Physical Chemistry

A PROGRAMME has now been arranged for the meetings which are to celebrate the twenty-fifth anniversary of the French Society of Physical

Chemistry, to which reference has already been made in these columns (Jan. 14, p. 53). Two general discussions will be held on Oct. 16–22, on "The Electron Theory of Metals" and on "Electrolytes and Boundary Layers (Electrode-Solution)". Among those who have already promised contributions to the discussions are Prof. Brillouin (Paris), F. Bloch (Leipzig), Prof. V. Henri (Liège), Prof. Joffé (Leningrad), Prof. E. K. Rideal (Cambridge), Prof. M. Volmer (Berlin), Prof. P. Debye (Leipzig), Prof. P. Dutoit (Lausanne), R. Audubert (Paris), Prof. F. Dubois (Clermont-Ferrand), A. H. Wilson (Cambridge), Prof. A. Gillet (Liège), Prof. O. Scarpa (Milan), Prof. Denina (Turin), Prof. J. Heyrovský (Prague). Notification of proposed attendance at the meeting should be sent as early as possible to the General Secretary of the Society, Dr. Ch. Marie, 9 rue de Bagneux, Paris (VI). The registration fee is 125 francs, including reception, banquet, excursions, etc., as well as advance copies of papers for discussion. Advance proofs will be forwarded immediately to those who pay their registration fee before June 30; others will receive them at the meeting in October.

Sixth Imperial Social Hygiene Congress

THE sixth Imperial Social Hygiene Congress will be held at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1 on July 3–7 under the presidency of Sir Basil Blackett. On July 3, the presidential address will be delivered, and the rest of the Congress will be divided into a series of discussions including such topics as the effect on established social customs of modern knowledge and economic conditions; changes in the outlook on prostitution; biology and health—the teaching of biology in schools and colleges; conference of teachers of biology; methods of dealing with venereal disease in the defence forces of different nations; the training, etc., of health visitors, nurses and midwives; venereal disease administration and the supply of educational and cultural films. Progress reports from Great Britain and the Dominions concerning different branches of social hygiene will be presented at the Congress. Arrangements have been made for visits to various institutions of interest to the delegates, a special display of films, and an exhibition of simple equipment used in biological teaching. Further information concerning the Congress can be obtained from the Secretary, British Social Hygiene Council, Carteret House, Carteret Street, London, S.W.1.

Announcements

AT a meeting of the Royal Society held on May 25, the following were elected foreign members of the Society: Prof. Vilhelm Friman Koren Bjerknes, of the Physical Institute of the University of Oslo; Prof. Harvey Williams Cushing, of New York, distinguished for his work on the surgery of the brain; Prof. Peter Debye, professor of physics in the University of Leipzig; Prof. Friedrich August Ferdinand Christian Went, professor of general botany in the University of Utrecht.

THE annual visitation of the National Physical Laboratory will take place on June 27 from 3 to 6 p.m.

THE RIGHT HON. LORD MELCHETT has consented to accept the presidency of the British Science Guild in succession to the Right Hon. Sir Samuel Hoare, whose three-year term of office ends this month. Lord Melchett will be elected president of the Guild at the annual general meeting to be held in the Mansion House on June 19 at 4.30 p.m. when the Right Hon. The Lord Mayor of London (Sir Percy W. Greenaway) has kindly agreed to take the chair.

AT the anniversary meeting of the Linnean Society of London held on May 24 the following were elected officers of the Society:—*President*, Prof. F. E. Weiss; *Treasurer*, Mr. Francis Druce; *Botanical Secretary*, Mr. John Ramsbottom; *Zoological Secretary*, Dr. Stanley W. Kemp.

THE annual general meeting of the British Science Guild will be held in the Mansion House, London, E.C.4, on June 19, at 4.30 p.m., when the chair will be taken by the Right Hon. the Lord Mayor of London. The meeting will be followed by a popular lecture entitled, "Some Problems of British Forestry", by Prof. R. S. Troup, professor of forestry in the University of Oxford and director of the Imperial Forestry Institute.

APPLICATIONS are invited for the following appointments on or before the dates mentioned:—An assistant lecturer in mathematics at the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (June 12). A director of research at the Forest Products Research Laboratory, Princes Risborough—The Secretary, Department of Scientific and Industrial Research, 16, Old Queen Street, Westminster, S.W.1 (June 22). A lecturer in pathology at the University of Liverpool—The Registrar (June 24). A head of the Manual Training and Engineering Department of Christ's Hospital, Horsham—The Headmaster. An assistant lecturer in agricultural botany at the University of Reading—The Registrar. A part-time teacher of bakery science (especially elementary physics and chemistry) at the Borough Polytechnic, London, S.E.1—The Principal. A head of the Mining Department at the County Technical College, Mansfield—The Principal. A lecturer in biology and some mathematics at the Stockwell Training College, London, S.W.9—The Principal. External examiners in scientific, medical and other subjects for various degree examinations in the University of London—The External Registrar, University of London, South Kensington, S.W.7 (July 3).

ERRATUM.—In NATURE of May 27, p. 764, twelve lines from foot of first column, for "*nn* higher unstable and lower grades" read "unstable *nn* higher and lower grades".

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Fibres from the Coat of a Blackface Lamb

IN the course of the study of the lamb's coat of various breeds of sheep, a range of fibre forms has been recognised by Duerden and Dry. In this method of classification, the apparent thickness of the fibres is of great significance; but analogous to results obtained from work on crimp, it is now suggested that it may not be entirely ascribed to increase of cross-sectional area, but may be due to a twist of the fibre. Thus a thick or thin filament would appear according as the major or minor axis of the cross-sectional ellipse was seen. Prof. Duerden kindly supplied typical prototrichs from the fleece of a Blackface lamb aged 1 month.

The specimens examined were taken as being characteristic of the extreme types of fibres of the Duerden range. The fibre was observed at magnification 500 at marked points along its length and oriented at each point through 180°. The fibre thickness, the ellipticity and the circumference so measured, together with axial orientation, were plotted against distance along the fibre for each case examined.

Type (a), or sickle tipped fibre : Visually the fibre may appear as being composed of three parts along its length : (*A*) the sickle-shaped tip, (*B*) a finer portion of the stem, and (*C*) a thick portion which is a definitive fibre or fibre proper.

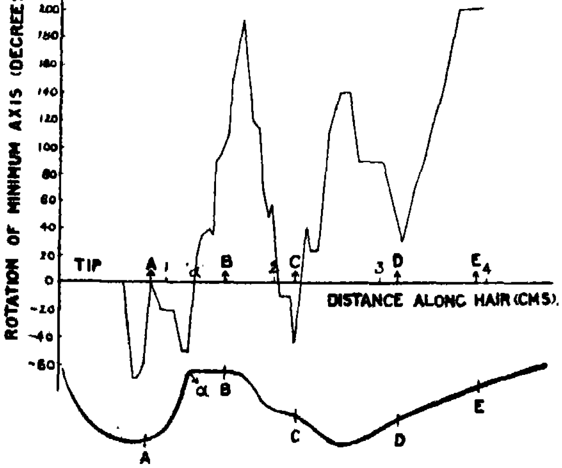

FIG. 1.

Measurement of cross-sectional area shows that the decrease in thickness from the tip to the next proximate portion of the fibre, if any, is of very small significance. Following this, the cross-sectional area of part (*C*), namely, the fibre proper, may be such that the final value is seven or eight times that at the sickle tip. Measurements of the angle or orientation of the minor axis of cross-section of a typical sickle tip fibre, kindly supplied by Duerden, are shown in Fig. 1, the diagram of the fibre below indicating the portion and visual appearance of the fibre examined. The angle of orientation follows the natural crimp of the fibre almost exactly.

Additional attention was paid to the point of inflection of this fibre, designated by α, namely, the point at which apparently the sharp transition takes place from the thick sickle tip to the thinner filament, and where a sharply defined bend occurs in the fibre form. The two photomicrographs, Fig. 2, were taken at the point α in two directions at right angles to each other; coincident points, *a*, *b*, *c*, *d*, *e* and *f* are marked on each picture. A comparison of the two pictures shows clearly what has happened. A thick place when viewed in one plane becomes a thin place when viewed at right angles and vice versa. The value of the circumference along this portion shows an almost constant value.

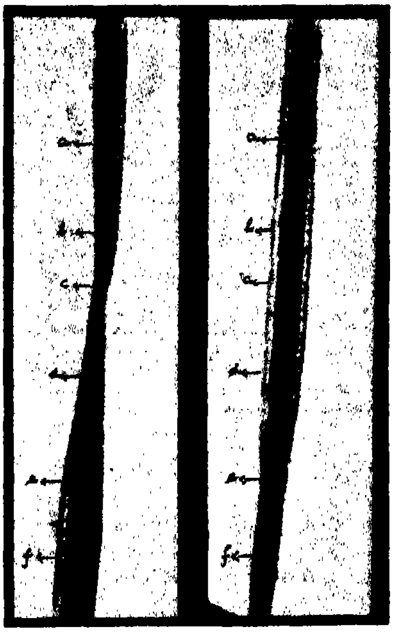

FIG. 2.

The point α is therefore in reality a place of concentrated twist, that is, there is not a sudden decrease of thickness at this point, but a sharp rotation of the axes of the cross-sectional ellipse about the axis of the fibre length. The later increase in thickness at part (*C*) is real, and not due to rotation.

Type (b), sickle tip not evident : Samples provided by Prof. Duerden were longer in length than the sickle tip fibres, taken from the same animal ; they were about 6·5 cm. long as against 4·5 cm. In these fibres the thickness shows no sudden changes, but a gradual increase along the whole length of the fibre. The ellipticity, in contrast to that of the sickle tip fibres, initially increases (not decreases) in value, and then settles down to oscillate about an average. In sickle tip fibres the ellipticity is high distally and decreases rapidly proximally. The orientation of the axes again closely follows the natural crimp. It would seem that in the sickle tip fibres, type (*a*), the end portion shows an apparent thickening, due to visual presentation of the major axis to the eye, whilst lower down the fibre the apparent attenuation is a consequence of viewing the minor axis. The same point on such a fibre viewed in a plane at right angles to the first, shows a reversal of these dimensions.

In consequence of these observations, classification of fibres according to their apparent tip thickness becomes a matter for careful consideration as to whether such variations are real, or are associated with fibre twist of a concentrated character at a particular point, or due to both twist and variation of ellipticity of the cross-sectional contour.

Miss A. L. Walker carried out most efficiently the measurements recorded.

Presence of Formaldehyde in Dew

LAST year we reported the presence of formaldehyde in rain-water[1]. We have observed that the amount of formaldehyde in freshly collected rain-water varies from 0·00015 to 0·001 gm. per litre.

Recently we analysed ten samples of dew collected at Allahabad, which is a comparatively dry place. The amount of dew collected was small and was about 10 c.c. in each case. In every sample of dew collected so far, formaldehyde could be detected at once by Schryver's test. On carrying out comparative experiments, we could estimate approximately the amount of formaldehyde present in dew. The amount of formaldehyde in dew is appreciably greater than that present in rain water. In most of the samples of the dew analysed the amount was approximately 0·0015 gm. per litre.

It appears that formaldehyde in dew comes from air in contact with grass, leaves, soil, etc. It is well known that almost all organic substances in the wet condition when exposed to light and air form formaldehyde. The origin of this formaldehyde has not yet been satisfactorily explained. We are of the opinion that organic substances, which are rich in energy, when exposed to light and air, are oxidised by atmospheric oxygen to carbon dioxide and water. The freshly-formed carbon dioxide appears also to be rich in energy, and with water can undergo photosynthesis to formaldehyde in presence of light more readily than ordinary carbon dioxide present in the atmosphere. That is why formaldehyde is more easily detected in the photo-oxidation of organic substances, which give out energy in their oxidation, than in the case where ordinary carbonic acid or bicarbonate solutions are exposed to light. In some cases, however, such as the photo-oxidation of glycine, formaldehyde, apart from photosynthesis, may also be obtained as a direct product of its photo-oxidation; but in the majority of cases in the photo-oxidation of organic substances, formaldehyde is likely to be produced from the photosynthesis of the energy-rich carbon dioxide and water which are products of photo-oxidation in presence of sunlight. The formaldehyde produced in this way will be present in the air which comes in contact with organic matter present on the surface of the soil, wet leaves, grass, etc.

Constitution of Dehydro-Ascorbic Acid

SOME time ago[1] we found that by the action of a copper acetate solution upon ascorbic acid, a dehydro-ascorbic acid is formed, which has the formula $C_6H_6O_6$, that is, it has two hydrogen atoms less than ascorbic acid. The determination of the free hydroxyl groups according to Zerewitinoff, shows for the dehydro-acid only two hydroxyls, in contrast to the original acid which gives four. One of the two hydroxyls removed by oxidation is the enolic hydroxyl, which is responsible for the reducing power of ascorbic acid.[1]

The dehydro-ascorbic acid is most likely an inner peroxide; which would account for its oxidative qualities.

According to Micheel and Kraft[2], oxidation of ascorbic acid to dehydro-ascorbic acid should lead to the formation of a new hydroxyl group. This is erroneous.

Rôle of the Solvent in Electrolytic Dissociation

IN a letter to NATURE of April 22, Dr. A. R. Martin has discussed the interpretation to be placed on the experiments of Hughes and Hartley[1] on the effect of small additions of water on the electrical conductivities of salts in methyl alcohol and acetone.

We have recently completed a series of determinations of the conductivities of lithium chloride in water – ethyl alcohol mixtures extending from pure water to pure alcohol, and the results have some bearing on this question. We find that the electrical conductivity at infinite dilution varies very nearly inversely with the viscosity of the solvent, that is, $\Lambda_0\eta$ is constant, in solvents containing up to about 20 mol. per cent alcohol. As the proportion of alcohol is increased, $\Lambda_0\eta$ then decreases continuously to its value in pure alcohol. This adds further support to the view, previously based on measurements of the partial vapour pressures[2], and of the molar volumes and molar refractivities[3] of lithium chloride in these solvents, that, until more than about 20 mol. per cent of alcohol is present, the ions remain solvated almost entirely by water, but as the proportion of alcohol is further increased, alcohol molecules enter the 'solvation sheath' of the ions to a steadily increasing extent. In the case of potassium iodide, $\Lambda_0\eta$ increases appreciably with the first additions of water, but it afterwards decreases and for the greater part of the concentration range the curve follows the same course as that of lithium chloride.

In connexion with Dr. Martin's remark that the extent of dissociation is determined by the free energies of the ions and undissociated molecules in the solvent, and that the solvation of an undissociated molecule may be a factor comparable with the solvation of an ion in these quantities, an extreme case, recently investigated by Hamilton and Butler, is of some interest[4]. It was found that zinc chloride, although a typical strong electrolyte in water and practically a non-electrolyte in alcohol, has nearly the same free energy in the two solvents. The consequences of this are interesting.

Let $(H_M)_W$, $(H_I)_W$ be the solvation energies of the undissociated molecules, and of the ions in water, and I the ionisation energy in the gaseous state. Then if F_W is the energy of ionisation in water, it is evident from the accompanying scheme that $F_W = (H_M)_W - (H_I)_W + I$. Similarly for another solvent A we have $F_A = (H_M)_A - (H_I)_A + I$.

$$\begin{tikzcd}
ZnCl_2 \arrow[r, dashed, "I"] & Zn^{++} + 2Cl^{-} & \text{In the gas.} \\
ZnCl_2 \arrow[u, "(H_M)_W"'] \arrow[r, dashed, "F_W"] & Zn^{++} + 2Cl^{-} \arrow[u, "(H_I)_W"'] & \text{In water.}
\end{tikzcd}$$

If the salt is largely dissociated in W and practically undissociated in A, F_W must be large and negative and F_A large and positive. Since the free energy of the ionised salt in W is about the same as that of the unionised salt in A, we also have $(H_M)_W = (H_I)_A - I$. These two requirements are only satisfied if

$$(H_I)_W > (H_I)_A, \; (H_M)_A > (H_M)_W,$$

that is, the solvation energy of the ions must be greater in W than in A, while the solvation energy of the undissociated molecules must be greater in A than in W.

Can such a state of affairs arise from the action of the dipole forces, or is it necessary to invoke some chemical interaction between the undissociated molecules and the solvent A?

Priestley as a Practical Chemist

NOT enough attention has been paid, in studying the work of Priestley in chemistry, to his admission that he was "not a practical chemist". He made that admission again and again—and amplified it—in scientific memoirs, in the memoirs of his life and in letters. The following list of references to the point should be of use to those who study Priestley: (1) "Philosophical Empiricism", etc., 1775, pp. 24, 26; (2) "Experiments and Observations", etc., 1775, p. I (reproduced in "Experiments and Observations", etc., 1790, 2, p. 295); (3) "Experiments and Observations", etc., 1779, p. 134 (*cf.* "The Collected Papers of Carl Wilhelm Scheele", trans. by Dobbin, p. 302); (4) Bolton, "Correspondence of Priestley", p. 124 (a letter, dated 12.1.1792, sent to Keir); (5) Thorpe, "Humphry Davy, Poet and Philosopher", p. 39 (a letter, dated 31.10.1801, sent to Davy); (6) "Memoirs of Dr. Joseph Priestley written by himself", Centenary edition, 1904, p. 40, par. 101. I suppose that other references to the same point are to be found.

What I call an admission, Prof. Patterson takes to mean that Priestley was not "a person who made his living by the preparation and selling of chemical compounds—a professional chemist" (NATURE, May 13).

Priestley said, writing to Davy: "As old as an experimenter as I am, I was near forty before I made any experiments on the subject of Air, and then without, in a manner, any previous knowledge of chemistry. This I picked up as I could, and as I found occasion for it from books." He said in his "Memoirs": "if I had been previously accustomed to the usual chemical processes, I should not have so easily thought of any other; and without new modes of operation I should hardly have discovered anything materially new". In the "Philosophical Empiricism" he reports that he made the acquaintance of Dr. Bryan Higgins: "I told him that, not being a practical chemist, having never had a proper laboratory, or seen much of the usual processes, I wished to have an opportunity of observing some of them: but that I more especially was in want of *chemical articles*, such as I could not easily procure at the shops."

There should be no difficulty in seeing what was meant. Priestley had a poor knowledge of chemistry—the orthodox thing—that was concerned with solids and liquids: the gases were beyond its pale. He could pursue the study of gases with the minimum of reference to the orthodox chemistry: what he needed of it he picked up as he went along. He made numerous acknowledgments of assistance that he got from friends, in learning the ordinary processes of a chemical laboratory. A certain instance is instructive. He commenced work in chemistry—upon gases, that is—in the year 1767. From nitric acid he obtained nitric oxide in the year 1772 and oxygen in March 1775. He learnt how to prepare nitric acid, with the guidance of Mr. Winch, jun., at the end of the year 1775 ("Experiments and Observations", etc., 1777, pp. 234–7).

Some Effects observed in Mice under Continued Treatment with Œstrin

DURING a recent inquiry at this Institute into the comparative effects of œstrogenic and carcinogenic substances on mice, some observations were made which suggest that œstrin brought about hernia in some of the animals.

The keto-hydroxy-œstrin employed in this experiment (for which we are indebted to the generosity of Dr. Girard) was made from the urine of pregnant mares and had a specific rotation $[\alpha]_D = +178°$. When injected into rats by the method described by Allan, Dickens and Dodds[1] it was found that 0·4 gamma gave a response in 50 per cent of ovariectomised rats. This corresponds to the figure usually given for the standardisation of crystalline keto-hydroxy-œstrin when employing the method described in that paper on a certain strain of rats.

Eight male mice were treated with subcutaneous dosage of œstrin in the right groin. During ten weeks five injections were given, each consisting of 0·5 c.c. of a 0·3 per cent solution of keto-hydroxy-œstrin in olive oil. At the end of this time, five of the eight mice were found to have bilateral scrotal hernias, their scrotal sacs being distended by viscera which normally are retained within the abdomen.

During the same period 28 male mice received applications twice weekly of a solution (0·3 per cent in benzene) of the same œstrin to the non-epilated skin of the interscapular region by means of a small paint brush. After ten weeks of this treatment, three of these mice had scrotal hernias, bilateral in one and unilateral in the other two. Examination of 90 untreated stock mice and 276 mice under treatment of various kinds not entailing the use of œstrin did not reveal a single scrotal hernia.

The same solution of œstrin in benzene applied twice a week in a similar way and for the same period to the non-epilated skin of 10 female mice not only kept them in œstrus, as tested by the ordinary smear method, but also led in some instances to an accumulation in the vagina of a mass of keratinised epithelium sufficiently large to distend the canal and to block the outlet from the uterus, both horns of which were distended considerably with fluid. These results indicate that keto-hydroxyœstrin in such a medium is readily taken up through the healthy skin, although it is impossible to ignore the possibility that some may have been taken up by the alimentary canal through the mice licking one another.

The hernias in the male mice treated with superficial applications of œstrin, and those in the mice treated by subcutaneous injection, may be reasonably attributed, it seems, to the action of œstrin. The phenomenon may have some connexion, perhaps, with the well-known fact that in certain species the pelvic ligaments are softened during pregnancy, when large quantities of œstrin are circulating in the body.

Occurrence of Ovulation without 'Heat' in the Ewe

A RECENT study of reproductive phenomena in the ewe has shown that, in this animal, ovulation occurs regularly during the month previous to the commencement of the breeding season, and occasionally during the breeding season, without the exhibition of mating. The premises for this conclusion may be stated briefly as follows:—

(1) Four out of five ewes killed before their breeding seasons had commenced showed healthy corpora lutea in their ovaries.

(2) In seventeen ewes kept constantly with a vasectomised ram, the vaginal secretions underwent one or more cycles of œstrous changes before the first 'heat' period had occurred. These cycles possessed the periodicity characteristic of the normal œstrous cycle.

(3) Five of these ewes killed during the breeding season showed, in their ovaries, either one or two more 'generations' of corpora lutea than could be accounted for by the number of full œstrous periods through which they had passed.

(4) The diœstrous interval is sometimes twice, and rarely three or four times its normal length. It is thought that multiplication of the cycle interval takes place as a result of the occurrence of ovulation and the development of corpora lutea although œstrus does not occur.

There is evidence to suggest that under highly favourable nutritive conditions, such as are constituted by the farming practice of 'flushing', these spurious ovulation periods may be converted into normal œstrous periods at which the mating instinct is exhibited.

Cole and Miller[1] have found that a single injection during anœstrus of serum from pregnant mares containing 50 'rat-units' or more of gonad-stimulating substance, causes ovulation although 'heat' does not ensue.

Observations made by Mr. Wm. C. Miller (unpublished) have shown that the ovaries of red deer hinds killed during early pregnancy commonly contain not only the corpora lutea of pregnancy but also one or more 'generations' of atrophic corpora. Since it is probable that in the wild state very few hinds fail to conceive at the first service, this fact suggests that the phenomenon of ovulation in the absence of mating may not be confined to the ewe.

Full details of the investigation will be published shortly.

The Minor Details of the Planet Mars

IN the issue of NATURE for April 8, p. 518, a note appears on an article on Mars by Mr. H. B. Brydon, in which particular reference is made to my recent volume on the planet and my conclusions as to the illusory nature of the so-called canals. In order that readers of NATURE should not be misled by the article, I hasten to reply to Mr. Brydon's statements.

It is at Flagstaff that the planets Mercury, Venus, Jupiter and Saturn, as well as the Jovian satellites, have been seen covered with linear markings, which were afterwards pronounced unreal by their most prolific discoverer[1]. It is further imprudent for a believer in linear canals on the planet Mars to mention the name of Prof. G. W. Ritchey, since that great astronomer repeatedly asserted to me that, having carefully scrutinised Mars with the fine 60-inch reflector of Mount Wilson, constructed by himself, he never saw a single straight line, or canal, on the planet, though details were observed beyond the range of the most powerful refractors in existence.

My late-lamented mentor and friend, E. W. Maunder, remarked in 1894 that the so-called canals of Mars often disobey the laws of perspective; and I have demonstrated in my book the veracity of this statement, by showing that canals considered to run along arcs of great circles appear straight, not only at the centre of the disc, but also at 30° and more from the centre—a fact which, of course, establishes their illusive character.

I have also shown that the canals, after defying perspective, further defy diffraction, since they vanish in a large telescope, whereas a real, dark, planetary line, such as Cassini's division of Saturn's ring, becomes naturally darker and broader with an increase of aperture.

Lastly, I pointed out in 1909 that, in the 33-inch refractor I was using, no straight lines could be detected on Mars, while delicate detail, far beyond the reach of the small telescopes with which the illusory canals had been discovered, was held quite steadily under fine seeing.

Such objections, whether considered severally or collectively, are, of course, fatal to the alleged reality of the linear markings. The planet is far too distant, from 35 to 250 millions of miles, to show canals. The truth is that a tired eye is liable to glimpse straight dark lines on the so-called continental regions of that neighbour world when viewed through an ordinary telescope; but these optical illusions vanish in a powerful instrument, which reveals broad, complex, dusky streaks, forming no network on the planet. The surface features of Mars are thus shown to be infinitely irregular and natural, like those of all the other bodies of the solar system.

Electron Diffraction by Vapours

DURING the last two years, a practical method has been evolved for obtaining good photographs of the diffraction of 30–55 kv. electrons by vapours. I now get satisfactory results with any substance the vapour pressure of which exceeds 10 cm. of mercury at 750° C. With the aid of the apparatus now set up, measurements of the electron diffraction of any known stable organic compounds can be made, and the investigation of many interesting structural problems arising in inorganic chemistry is also rendered feasible. A number of preliminary photographs have been taken of members of the following series and of certain other substances: Polyhalogen derivatives of methane and ethane; aromatic hydrocarbons and some of their isomeric dihalogen compounds; polymethylene dibromides from butane and decane; and volatile halides of the elements and of cyanogen.

It has recently been found that nearly double the number of diffraction rings that have been observed up to now can be registered by using a variety of photographic emulsions. Hence most of the work must be repeated before the full results can be published in detail.

Viscous Damping of Vibrating Metal Bars

WITH the exception of those made by K. Honda and S. Konno[1] and also those by K. Iokibe and S. Sakai[2], few measurements of viscous damping in metals have been made. I have made some experiments concerning this problem with the assistance of Mr. K. Kubo[3]. The metals experimented with were aluminium, duralumin, copper and brass, each in the form of a bar clamped at one end and free at the other. To analyse the result the appropriate solutions of the following equation were used:

$$\rho\frac{\delta^2 y}{\delta t^2} + Ek^2\frac{\delta^4 y}{\delta x^4} + \xi k^2\frac{\delta^5 y}{\delta t\,\delta x^4} + \zeta\frac{\delta y}{\delta t} = 0,$$

where E is Young's modulus, ξ the coefficient of solid viscosity, ζ the coefficient of air damping, k the radius of gyration of a cross section of the bar, and y the deflection of the bar at x.

Vibration experiments were made in a vacuum chamber of inner diameter 40 cm., inner height 24 cm., and thickness 1 cm. A circular hole of 3 cm. diameter in the vertical wall of the chamber was plugged with a disc having parallel plane surfaces, through which the movement of the test piece in the chamber was observed. The air in the chamber was pumped out through a pipe system connected to a Cenco Megavac pump and a glass Langmuir diffusion pump, by which the pressure was lowered to 1/2,000 mm. of mercury. Special arrangements for the clamping and the motion of the bar as well as the photographic recording were devised.

The results, after analysis, showed that the coefficient of solid viscosity ξ in C.G.S. units is $7{\cdot}5 \times 10^6 \sim 8{\cdot}0 \times 10^6$ for duralumin, $5{\cdot}9 \times 10^6 \sim 6{\cdot}8 \times 10^6$ for aluminium, $9{\cdot}3 \times 10^6 \sim 11{\cdot}6 \times 10^6$ for copper, and $12{\cdot}7 \times 10^6 \sim 15{\cdot}0 \times 10^6$ for brass. It was also found that the coefficient of solid viscosity is different for different amplitudes of vibration. For large amplitudes the coefficient was also large.

From this work it will be seen that the values of the solid viscosities of metals are so small as to be of the order of $10^6 \sim 10^7$ in C.G.S. units. If the energy of vibration is dissipated outwards from the clamped end, the value will be apparently increased to a much greater degree. In an aeroplane flying in air or in analogous cases, little energy can be dissipated outwards, while the inner damping is too small, so that it is probable that the phenomena of perfect resonance will frequently take place. In the case of a building or of a machine on land, the dissipation of vibrational energy is not the effect of the viscous or other frictional damping but is chiefly due to the radiation of the energy from the boundary, so that the synchronous vibration in that case does not play an important part in the nature of the building or machine. The explanation of the increase of damping with the increase of the amplitudes of vibration is somewhat difficult in the present state of our knowledge on mechanics.

Supersonic Vibrations set up in a Zinc Bar undergoing Transverse Vibrations

IN the course of experiments on the latent splitting of bars as reported by one of us[1], we noticed a very curious and interesting phenomenon in zinc.

When the zinc bar after observations of frequency had been removed, we noticed on examining it that besides rupture lines, a large number of indentations and protuberances were clearly visible at very regular intervals along one of the vertical sides of the bar. It had the familiar appearance of the

FIG. 1.

Kundt's tube phenomenon, where nodes and antinodes are formed by the stationary longitudinal vibrations of the enclosed gas. The protuberances were shining spots formed by the bulging out of the zinc locally. The effect was photographed and is reproduced in Fig. 1 after enlargement. The distances between the successive nodes were measured directly on the zinc bar by means of a microscope.

As the reproduction shows, these nodes and antinodes are at extraordinarily regular intervals. The mean value of the distance between consecutive nodes came out to be 0·141 cm.

Now the velocity of longitudinal waves or the velocity of sound in a material is given by

$$V = \sqrt{E/\rho}$$

where E is Young's modulus and ρ the density of the material. But the velocity V of the longitudinal waves is also given by

$$V = n\lambda$$

$$\text{Therefore, } n^2\lambda^2 = E/\rho$$

Substituting the values of E and ρ for zinc and of λ as found from actual measurement, we get the value for frequency

$$\begin{aligned} n &= \sqrt{\frac{8{\cdot}7 \times 10^{11}}{7{\cdot}1 \times (0{\cdot}282)^2}} \\ &= 1{\cdot}24 \times 10^6 \end{aligned}$$

This high frequency, of the order of a million, is probably due to the impact of zinc crystals in the bar during the course of alternate compression and extension in the act of vibration.

The frequency of transverse vibration of the zinc bar had been varied from nearly 78 to about 27 and the appearance reproduced in Fig. 1 was formed during the course of this variation. The thickness of the bar was 0·066 cm.

We made a few attempts to reproduce the phenomenon noted here, but have not been successful so far. It is possible that there is a critical frequency of the transverse vibration of a given bar for which the longitudinal vibration excited is the strongest, depending on the size of the metal crystals contained in the bar. It may be noted here that it is well known that metallic zinc contains ordinarily well-developed crystals.

Characteristics of the Ionosphere

IN the course of recent experiments[1] on the structure of the ionosphere, we have found that not two only but several[2] 'layers' exist in which there is either a maximum, or a tendency towards a maximum, of ionic density. Since any complete theory of the structure of the upper atmosphere or of the transmission of radio waves through it must take these facts into account, it is thought that a brief summary of the results will be of interest. Certain observations concerning abrupt variations of ionisation will also be described. In all these experiments transmission was at normal incidence to the layers.

(1) It has been found that in addition to the E region at a height of 100–120 km. and the F region from 190 to 300 km. there is an intermediate reflecting region, which we shall refer to as the M region. The data indicate that the average height of the M region is approximately 150 km. but that on some days it may be so high as 180 km. while on other days it may be so low as 130 km. The M region has been found on a number of occasions before noon during December of last year and January and February of this year. The data usually indicate that when this region is found there is a well-defined maximum of ionic density and that it is separated from the E and F regions by ionisation minima.

In order to observe the M region, it is necessary that the frequency used be great enough to permit penetration of the E region, but small enough to give reflection from the M region. The M region can, therefore, be observed only so long as its maximum of ionic density exceeds that of the E region below it.

As the maximum ionic densities of the E and M regions have been found to be of the same order of magnitude during the times when they are both observed, and as the maxima do not vary at the same rate with time, it is reasonable to assume that the M region maximum is normally present but that it is shielded by the E region except for a few hours in the middle of the day.

(2) The ionisation in the F region does not increase uniformly with height but has often been found to have a step-like structure[3]. This indicates that there is a tendency for the formation of several ionisation maxima in the F region. Occasionally two maxima have actually been found, but ordinarily these subregions overlap and the ionisation increases in a series of 'steps'. At times the 'treads' of this step-like structure are strikingly level, indicating remarkably abrupt ionic density gradients at heights near 200, 240 and 280 km. This type of phenomenon has been found only during daylight hours, and it may be said that if the steps are present at night they are very difficult to find. These facts suggest that the formation of these subregions depends upon the ionising activity of the sun.

(3) Throughout the daylight hours during the past winter the ionisation of the F region has often been found to vary in an erratic manner. The maximum ionic density exhibits abrupt changes which are often so great as 25–50 per cent within time intervals of 15–30 minutes. These changes suggest that there may be some variable source of ionisation, cosmic or solar in nature, the effect of which is superimposed upon a normally steady ionising effect due to the sun. The time of maximum ionisation seems to occur near noon, but the maximum is not at all well-defined, since the ionic density has about the same average value from 9.00 a.m. until 3.00 p.m. (winter and spring at Deal, N.J., latitude 40° N.).

(4) The ionisation of the E region increases with time in a uniform manner, attaining a maximum near noon. The abrupt changes found in the F region are not normally present in the E region.

[1] The method used was that previously described in the *Proc. Inst. Radio Eng.*, July, 1932.

[2] This had previously been suspected for days of magnetic storms (*loc. cit.*, p. 1145).

[3] T. L. Eckersley also has concluded that the F region may be stratified. See *J. Inst. Elec. Eng.*, vol. 71, September, 1932.

Output of Electrical Energy by Frog-Skin

IF a piece of frog-skin, mounted with glucose Ringer solution on both sides, is connected in series through two calomel electrodes with a micro-ammeter, a current may be observed to flow through the circuit for many hours. With a piece of skin 1·6 cm.^{2} in area in a circuit of total resistance 1,500 ohms the current is 20–30 × 10^{-6} amperes during 12 hours after setting up.

Between 0° C. and 30° C. the resistance of the skin falls steadily, the potential rises to a maximum at about 20° C. and then falls off, and the current rises to a maximum at about 25° C. before decreasing. The output of electrical energy by the skin can be calculated as equivalent to the Joule heat developed in the circuit. This was found for four different skins to lie between 5 and 9 × 10^{-8} calories per minute per gram dry weight of ventral skin at 20° C. It has been shown[1,2,3] that when the *ionic composition* of the solution is constant the frog-skin potential is maintained by oxidation processes. It is of interest, therefore, to see what fraction of the energy released by oxidation may appear as electrical energy. The respiratory quotient of the skin of *Rana temporaria* is 0·97[4]. The average oxygen consumption of frog-skin[3] was found to be 20 × 10^{-3} c.c. oxygen per minute per gram dry weight at 20° C. (other values are summarised by Adolph[5]). Assuming that molecules of $(C_6H_{12}O_6)_n$ are burnt and taking the heat of combustion per gram as 680,000 calories, it will be found that the energy released by oxidation processes is on the average 100 × 10^{-8} calories per minute per gram dry weight at 20° C. The electrical energy output calculated above is 5–10 per cent of this value.

The temperature coefficient of the electrical energy output for a rise of 10° C. was determined for three skins and compared with the average Q_{10} for respiration for four skins.

	Q_{10} Electrical Energy			Q_{10} Energy from Combustion.
0° C.-10° C.	2·85	1·99	3·90	3·6
10° C.-20° C.	1·4	1·44	1·41	2·0
20° C.-30° C.	—	—	—	1·9

The power output is a maximum at 24° C. for the electrical process and at 38° C. for the respiratory processes of the skin. Lund and Moorman[6] have found that values of Q_{10} for potential and oxygen consumption of the skin of *R. pipiens* between 16·4° C. and 26·4° C. are 2·14 and 2·01 respectively. (In my work Q_{10} for the potential in this interval is near unity.) They adduce this approximate equality in support of a theory of the skin potential based on "the flux equilibrium of the oxidation-reduction systems" in the cells of the skin. Since, however, the frog-skin does not behave as a reversible galvanic cell, the potential cannot be related directly to the energy released by oxygen consumption except on the lines indicated above.

There are also objections to the interpretation of the skin potential, which is measured between reversible calomel electrodes, in terms of oxidation-reduction potentials which can only be measured with the aid of an inert metal electrode to act as an electron donor or acceptor[8]. The skin potential, like the injury potential of crab's nerve[7], depends on oxygen consumption and also on the nature and concentration of the electrolytes present[8]. With these two factors in mind, further work is in progress in conjunction with Dr. R. J. Pumphrey, on the nature of the frog-skin potential.

The Astronomical Radiative Stability

ASTRONOMERS are doubtless not unaware of the enormous radiative uniformity that is demanded by the permanence of organic life on the earth. If the temperature at the earth's surface were altered even for a single season from its actual value about, say, 27° C. or 300° K., by 50° in excess or defect, all terrestrial organic life would be blotted out never to return. This would happen if even only once in the hundred million years demanded for terrestrial organic evolution the effective temperature of the solar radiating surface changed from the present mean value 6,000° K. by 1,000° in excess or defect, if it were a matter of steady state, while during the time of this change the stream of radiation incident on the earth would be altered in a proportion much greater. On current theories the difference between the top and bottom of the radiating solar atmosphere would be great in comparison with this figure, and lower down vast temperatures are soon reached. This shows how extremely steady the balance must be, and how slight the solar evolution must have been even in that vast time. As one result, the sunspot disturbances, even though they occupy only a very small part of the area of the solar disc, would have to be purely superficial phenomena. The output of radiation is very steady, as from a steady interior; yet the heavens are full of variable stars. Perhaps these considerations were remotely in view when long ago Whewell and Brewster were discussing the plurality of worlds, and Huxley championed the geologists against Kelvin.

The Combustion Problem of Internal Ballistics

IN a recent paper on the combustion problem of internal ballistics[1], we have attributed jointly to Love and Pidduck[2] a statement as to the importance of including both temperature and pressure in the rate of burning law for colloidal propellants. Their paper was published in two parts, and the statement in question was made in Part 2, which was entirely the work of Dr. Pidduck. Our reference, in consequence, was misleading, and we desire to correct the error.

Research Items

Dragons. In *Man* for May, Mr. G. D. Hornblower discusses the origin and distribution of the art-forms of the dragon. The conception of a blend of various forms of fierce and dangerous animals such as lion, eagle and snake appears in the earliest pictorial records of the Near East. In Mesopotamia its association with deities may attribute to them the qualities associated with each animal. Dragons are both evil, as Tiâmat, or beneficent, as in the wings (a dragon survival) of the sun disc in Egypt. On all the earliest cylinders animal forms predominate, much subject to distortion. Animal art disappears in Mesopotamia under Semitic influence, but reappears in Assyrian art, while it holds its position in Egypt and North Syria. Beyond Assyria in Urartu (Armenia), dragons, lions and aurochs pointing to Assyrian influence appear on the objects looted by Sargon II from Musasir. It has been shown that Mitanni-Khattite art extended to this region, and thence to the Medes and through them to the Achaemenids, this zone including the hilly country around Elam, the modern Luristan, whence come objects of art attributed to the Kassites of the Iron Age and to be related, through Armenia, to a northern or 'Scythian' region of this art-province. Nomad peoples gave to this animal art a new life and vigour. The Scythians compounded an ancient animal art, possibly descended from an ancient stone age art extending from Finland to Siberia, with the influences from Mesopotamia and formed the animal art called 'Scythian', later adopted and further modified by the Sarmatians. In the southern province the animal art developed the peculiar characteristic of the elongation convention. Scythian elements were introduced into China in the Ts'in and Han dynasties, when the Chinese began to ride horses and changed their military equipment. In this new phase of Chinese art two provinces are to be discerned, one in which the chief characteristic is a plain animal form rendered naturalistically, and a second in which objects are decorated in foreign style, but with a well-developed Chinese manner.

Tell-Billa. An account of the joint excavations of the University Museum, Philadelphia, and the American Schools of Oriental Research at Tell-Billa, which is to appear in the *Museums Journal*, Philadelphia, opens with a report on the pottery by Dr. E. A. Speiser in vol. 23, No. 3. Tell-Billa is a mound fifteen miles north of Mosul, the excavation of which began in 1930 after a preliminary reconnaissance in 1927. This had indicated the importance of this mound and the adjacent Tepe Gawra, eight miles away, for knowledge of pre-Assyrian civilisation north of Nineveh. The two sites in conjunction have furnished stratified evidence for the study of more than four millennia of north Mesopotamian history, extending from neolithic down to the Hellenistic period. Gawra is by far the older site, the occupation of Billa beginning only when 14 metres of occupation deposits had covered the site of Gawra. From about 3000 B.C. to the middle of the second millennium, the two mounds show a parallel course of development. By this time Gawra had become unsuitable for further occupation and was abandoned for Billa. The occupation levels at Billa have been followed down to virgin soil. These show seven main strata, which afford a series of pottery sequences demonstrating ceramic changes and development at Billa and also contact with the outside world. From the survey of strata 7 and 6 (the lowest), it is apparent that the differences between the two strata are chronological rather than cultural. The chalice, first painted, then incised, is the most characteristic ware of strata 7 and 6 and is found in the seventh stratum of Gawra and at Nineveh. In south Mesopotamia a painted fragment occurs at Fara, of which the earliest level falls within the Jemdet Nasr period preceding the early dynasties of Ur. The Jemdet Nasr fabrics also include the squat pot with sharply marked shoulder which is well established at Billa. The distribution of the chalice corresponds roughly with the Highland Zone and has been traced from Anatolia to Persia. It is evident from the relation of Billa and Gawra that the chalice folk were intrusive. From this time onward Billa was subject to a succession of invasions from the north and north-east, with an influx of cultural influence from the south in stratum 5.

Norwegian Oyster Pools. Important hydrographical and biochemical work in connexion with oysters is described in Bergens Museums Årbok, 1932. 1. Hefte ("Naturvidenskabelig Untersuchungen in Norwegischen Austern-Pollen", von Torbjørn Gaarder und R. Spärck). Two oyster pools were investigated, the Espevik-Poll and the Saelø-Poll, both connected with the Hardanger Fjord. The chief conclusions are that the meteorological conditions, especially light, have a dominant influence on the physico-chemical relations and consequently on the life in these pools, since the light regulates the assimilation efficiency of the phyto-plankton which is the food of the oyster. The brackish water layer on the surface varies in thickness according to the rainfall, and the light must penetrate this layer effectually in order to reach the salt-water layer in which assimilation takes place. In a good year, the temperature below the brackish-water layer may reach a high figure and the smaller green organisms up to 3μ which are the chief food of the larvæ will abound in spring and summer. Unfortunately, the same food is taken by the small animals, especially gastropod larvæ (*Cerithium* particularly) and mussel larvæ which flourish under the same conditions. Efforts are made to get rid of these. In the bad years with little sunlight, bacteria increase greatly and it is interesting to find that this coincides with outbursts of the dinoflagellate *Ceratium*, the molluscs being little in evidence. The results of these researches indicate that much may be done with the pools in the way of oyster rearing provided that there is sufficient sunlight, the natural conditions being such that usually the chemical food required by the nannoplankton is adequately represented with the exception of nitrates and phosphates, which can be increased artificially.

Cattle Blood-Sucking habit of a Bug. On the occasion of describing a new genus and species of Anthocoridæ (Hemiptera) from New Zealand, W. E. China discusses the feeding habits of bugs belonging to this family (*Ann. and Mag. Nat. Hist.*, April, 1933). They appear to be probably all predaceous on eggs and larvæ of other insects, and even on the adults of smaller forms, such as Aphididæ and Coccidæ. Thus, *Triphleps insidiosus*, Say, and *T. australis*, China, feed on the eggs of the false cotton boll worm, *Heliothis obsoleta*; the many species of *Anthocoris* found in flowers probably prey on the thrips which live there; *Piezostellus flavipes*, Reuter, occurring in granaries, probably feeds on eggs and larvæ of grain feeding Coleoptera and Lepidoptera, or perhaps on mites, etc. Many species live under bark, and such is the case of the new one described in the paper, *Maoricoris benefactor*, which preys on the bark-beetle *Acrantus opacus*, White. An extremely interesting member of the family is *Lyctocoris campestris*, which is commonly found in stables and cattle-sheds and is known to suck the blood of horses and cattle. This exceptional habit suggests a possibility that *Lyctocoris* may act as a transmittor of foot and mouth disease. While the evidence in favour of this novel hypothesis is purely circumstantial, experimental examination would be of considerable interest.

Karyology and Systematic Relationship. A series of eight papers mainly devoted to the chromosome morphology of various economic plants is found in the recently issued *Bulletin of Applied Botany, Genetics and Plant-Breeding*, Leningrad. Vakar has made a study of the chromosomes in various interspecific wheat hybrids, which throws further light on their relationships, *T. pyramidale* being near *T. turgidum* as *T. sphærococcum* is allied to *T. vulgare*. The paper by Senyaninova-Korchagina on the chromosomes of various *Ægilops* species has a bearing on the origin of the bread wheats. The tetraploid and hexaploid species of *Ægilops* possess only one pair of tri-articulate chromosomes and one pair with 'heads'. From evidence of this kind it is concluded that these species have arisen through interspecific crossing and subsequent doubling of the chromosomes in the hybrids. There is evidence also of a phylogenetic shortening of one chromosome arm into a head. The same author has studied the chromosomes of *Vicia faba* and the related *V. nanbonensis* and *V. serratifolia*. She finds that while, for example, the races of *V. narbonensis* from Glasgow and Transjordania are morphologically alike, their chromosomes differ in the ratios of arm length. An extensive study of the Trifoleæ by Chekhov shows that nine species of *Ononis* out of ten are tetraploid, one being octoploid (64). In *Trigonella*, nine species have 16 chromosomes and one 28, probably due to an association of four chromosomes in a tetraploid. In this group most of the polyploid forms are perennial and have larger fruits. Emme has similarly investigated the species of the subgenus *Euavena* and the pentaploid hybrids of *Avena*.

Thickness of the Greenland Ice. The Wegener expedition to Greenland in 1930–31 was the first to use experimental seismic methods for measuring the thickness of the ice-sheet. Dr. E. Sorge has now given some account of these experiments and their results (*Geog. J.*, April). Measurements of the thickness were made in twelve places at 12, 42, 62, 82, 120 and 400 kilometres from the west coast respectively. The last of the series was at the station of Eismitte in the heart of Greenland at an elevation of 3,000 metres. Apparently the most accurate measurements were taken at 120 km., where observations were numerous. At Eismitte the seismograph was put up in only one place but several readings were taken. Dr. Sorge believes that at the central station the ice-sheet is about 2,000 metres thick but admits that, owing to possible error in the readings, it may be any depth between 1,800 and 2,700 metres. Even the smaller figure suggests thicker ice than was expected. At the 120 km. station the ice is 1,600–1,800 metres thick and the rock floor has slopes up to 30°. It is clear that the land surface of Greenland is not highland throughout and that much of the interior is not so high as the ranges near the coasts. In fact, the shape suggests a plate with a broader and higher eastern than western edge. Dr. Sorge discusses the methods employed and possible sources of error in the observations. One of the chief difficulties seems to be the weight of the explosives required, which is a serious problem in transport to the interior.

Earthquakes of Northern Africa. The African continent is usually regarded as one of general stability at the present time, and, if we confine ourselves to earthquakes of the first order, the impression is probably justified. There are, however, various regions in which shocks of moderate strength are common, one of the most important being that which consists of the three northern countries of Algeria, Tunis and Morocco. Mme. A. Hée has given an interesting account of the work recently done in those countries (*Matériaux pour l'Étude des Calamités*, No. 28, pp. 291–337; 1932). Regular observations in Algeria date from 1911, when two Mainka horizontal pendulums were erected in the Observatory of Alger-Bouzaréah. In Tunis, the meteorological service collected reports on earthquakes from 1922 and a Mainka pendulum was installed at Tunis in 1926. Since 1929, the Institut Scientifique Chérifien has undertaken the collection of macroseismic observations, but no recording instrument exists in Morocco. Thus, our knowledge of Algerian earthquakes is at present the most complete, and Mme. Hée gives lists of 586 earthquakes between the years 1911 and 1931, distributed in 22 different zones, four of these shocks reaching intensities 9 or 10. The more active zones, as usual, border the regions in which the sea bed slopes most steeply.

Cosmic Rays. Year Book No. 31 of the Carnegie Institution of Washington contains a summary by Prof. A. H. Compton of the results which have been obtained by the nine observers who, with the aid of a grant from the Carnegie Corporation of New York, have been sent with identical sets of apparatus to representative portions of the earth's surface. The rays are found to be influenced by the earth's magnetic field and are stronger at the magnetic poles than at the magnetic equator. The increase of intensity of the rays with altitude has been found to continue to very high elevations. The bursts of ionisation, which have been investigated show that a single cosmic ray is capable of releasing at least 10^8 electron-volts of energy. The diurnal variation of the rays at mountain stations is found to be greater than those observed previously by observers at lower levels. Argon gas under pressure is found to be a much more sensitive detector of cosmic rays than other gases. On the whole, the observations are in favour of the view that cosmic rays are streams of electrified particles such as electrons or protons. See also NATURE of May 20, p. 713.

New Observations on the Heaviside Layer. Ratcliffe and White have recently described the results of a method for recording continuously the reflection of wireless signals from the upper atmosphere (*Proc. Phys. Soc.*, May). Short wave trains are radiated by a special transmitter and the pulses with their echoes are received at a station a few kilometres away and recorded by a cathode ray oscillograph. The time base of the oscillograph is synchronised with the pulses by controlling both transmitter and oscillograph from the same A.C. mains. A record was taken from the oscillograph on continuously moving photographic paper. The records show very clearly the behaviour of the ionised layers, and from examination of a number of records, the 'normal' summertime behaviour has been deduced. During the day, reflection takes place from the E layer at an equivalent height of about 120 km. In the evening, the reflection is gradually transferred to the F layer at about 260 km. The height of this region rises gradually and the echo splits into two components which rise and disappear successively. At sunrise this sequence is reversed. The E region reflection sometimes reappears during the hours of darkness, and this abnormal behaviour seems to be connected with an ionising agency quite different from that producing the daytime E region. It is possible that this agency may be the electric fields in the neighbourhood of charged rainclouds. Appleton and Naismith describe in the same journal measurements which they have been making for some time on the maximum ionic content of the Kennelly-Heaviside layer. The density of ionisation is connected with the critical wave-length below which the rays penetrate the lowest layer and are reflected at an upper layer. Observations were made once every week at about noon. The curve shows a summer maximum of ion density. The summer maximum ionisation was greater in 1931 than in 1932, and this may be correlated with greater sunspot activity in the former year. Occasions of abnormally high ionisation density are common during the summer months, and a fairly high correlation has been found between high ionisation and thunderstorm activity.

An Optically Active Inorganic Salt. Sulphamide, $SO_2(NH_2)_2$, behaves as a weak dibasic acid and if sodium rhodichloride, Na_3RhCl_6, is added to a solution of its sodium salt, the salt $Na[(H_2O)_2Rh(N_2H_2SO_2)_2]$ is formed. Since the residue $-NH.SO_2.NH-$ occupies two of the six octahedral co-ordination positions of the rhodium atom, the other two being occupied by water molecules, the acid radical in square brackets should give the usual *cis* and *trans* forms, in the latter of which the $-N_2H_2SO_2-$ groups occupy two positions in the plane, and one position in the plane and one axis, respectively. This configuration is dissymmetric and should exist in optical isomers. Mann (*J. Chem. Soc.*, April; see also NATURE, 130, 368, Sept. 3, 1932), who has prepared this salt, has resolved it into optical isomers by crystallisation with dextro and lævo α-phenylethylamine and with d-nor-ψ-ephedrine. The occurrence of molecular dissymmetry among purely inorganic compounds is very rare, since it is almost invariably dependent on the presence of suitably co-ordinated ring systems and these are difficult to form with entirely inorganic elements, or are insoluble. The new compound, therefore, is of unusual interest.

Astronomical Topics

New Minor Planet. A very interesting new minor planet 1933 HH, of the tenth magnitude, has been discovered at Johannesburg. Berlin R.I. Circ. 779 gives the following orbit deduced by H. E. Wood and Mr. Jackson:

Epoch 1933 May 8·0 U.T.

$$\left.\begin{array}{ll} M & 193{\cdot}5890^\circ \\ \omega & 157{\cdot}0834 \\ \Omega & 335{\cdot}9980 \\ i & 7{\cdot}6191 \\ \varphi & 23{\cdot}5206 \end{array}\right\} \quad 1925{\cdot}0$$

$$\begin{array}{ll} n & 2863{\cdot}962'' \\ a & 1{\cdot}15333 \end{array}$$

Ephemeris for 0^h U.T.

	R.A.			N. Decl.	
June 1	0^h	18^m	30^s	1°	1′
,, 9	0	34	48	3	10
,, 17	0	51	18	5	22
,, 25	1	8	12	7	37

The object appears to resemble planet 1932 HA in that it comes inside the earth's orbit at perihelion, but it is now near aphelion.

Seasonal Changes on Jupiter. The axis of Jupiter is so nearly upright to its orbit plane that seasonal changes in the usual sense cannot be conspicuous. There are, nevertheless, certain changes traceable on its surface that approximate in period to its orbital revolution. Mr. A. Stanley Williams, who has been a regular observer of the planet for about half a century, has recently given (*Mon. Not. Roy. Astro. Soc.*, March) a study of the changes in rate of rotation of the north tropical current on Jupiter. He notes that this region is free from disturbing influences such as are present in the zone of the great red spot, so that there is more chance of detecting seasonal effects. The study covers half a century, 1881–30, and includes observations from all available sources. The graph shows evidence of a periodic change of rate, with maxima in 1888 ($9^h55^m40^s$), in 1904 ($9^h55^m32^s$), in 1919 ($9^h55^m30^s$), and in 1928 ($9^h55^m33^s$). There were well marked minima in 1911 ($9^h55^m17^s$) and 1922 ($9^h55^m21^s$). The author has used also a few observations made in 1835 and 1862, and deduces that the length of the cycle of change is 12·4 years, and that in the mean the epochs of minimum period, or maximum velocity, are given by the formula $1909{\cdot}9+12{\cdot}4E$. The period given is distinctly longer than the time of revolution, which is 11·862 years, but the interval covered by continuous and exact observations is scarcely long enough for the excess to be regarded as established. It is still more in excess of the average sunspot period; this has been suspected to be associated with some of the changes on Jupiter, but apparently the changes in rotation time are not correlated with it.

Illumination of Nebulosity surrounding a Nova. Mr. B. M. Peck contributes a paper on this subject to the February number of the *B.A.A. Journal*. Many attempts have been made to obtain the parallaxes of novæ by the rate of expansion of the surrounding nebula. There are, of course, two cases: that of an actual driving out of nebulous matter, and that of the rendering visible of previously existing clouds. The paper discusses the latter case and shows that the circle of visible nebulosity first expands to a maximum radius, and then contracts again to a point; the times of expansion and contraction are equal. During expansion the light is highly concentrated towards the centre, during contraction it tends to become uniform. The outburst is assumed to occur within the nebula. The results will be similar in kind if the nebula is behind the nova, but if it is in front of it there will be no contraction. The paper treats the subject analytically.

Central American Research by the Carnegie Institution

A FEATURE to be noted in the most recent developments of archæological research in the field is an increase in specialisation, and where financial considerations will permit, the supplementing of the purely archæological work by research in other branches of science which can be made to assist in the interpretation of archæological results in their bearing on the general problem of the history of man and the development of his culture, whether considered regionally or in its broader aspect. Thus Dr. A. V. Kidder, in his report as chairman of the Historical Section of the Carnegie Institution of Washington (Year Book No. 31), remarks: "It is difficult to escape the conviction that only by coordinated research involving the cooperation of all the disciplines devoted to the study of man and the collateral support of many biological and physical sciences can we attain understanding of any given episode in human history."

It is on these broad lines that the Carnegie Institution is now promoting the study of the archæology of Central America. Investigations which were undertaken originally as a study of the archæology only of the Mayas of Yucatan, have been expanded to embrace, in addition, on an ordered scheme, the geology, geography and climatology of the area, the physical characters of the inhabitants, their physiological characters and liability to disease, their ethnological affinities, their languages and their mode of life and culture.

At Chichen Itzá, the principal zone of interest of the Institution in Yucatan, Dr. S. P. Morley was engaged in the examination of a building known locally as the 'Mercado', although there is no reason to think that its original use was that of a marketplace. It was probably a purely ceremonial building. It consists of a single vaulted chamber, no less than 250 ft. long, in which the architect had given full play to technically daring and bold ideas. Thus the vault is 15 ft. wide, the broadest span yet recorded for the Maya area. The building displayed the weakness of all other Maya buildings in placing too great reliance upon columnar beams of wood to carry the huge weight of the stone superstructure. The roof crashed even before the abandonment of the city; but its fall preserved intact a remarkable altar on which was sculptured in relief and brilliantly painted a procession of elaborately costumed captives, marching towards a centrally enthroned figure.

A second major undertaking at Chichen Itzá was the exploration of a building known as the 'Monjas' by Mr. John S. Bolles—a problem of considerable complexity, owing to the fact that a building, originally small, had been continually enlarged by alterations and additions until it became a veritable puzzle in massive masonry. Even on a superficial examination it showed five distinct periods of architectural modification.

From Chichen Itzá an expedition was sent to investigate the newly discovered site of Calakmul in the archæologically unknown region of south central Campeche. Two weeks were spent there. The site proved to be that of a very extensive Old Empire city, remarkable for the unprecedented number of its monuments. The dates of nearly fifty were deciphered, ranging from A.D. 364 until A.D. 550. It was evidently colonised from Peten. Its situation midway between Peten and northern Yucatan gives it great archæological importance.

Next to Chichen Itzá, the Institution's most important archæological centre in the Maya field is Uaxactun, an Old Empire city in Northern Peten, Guatemala, where work has been carried on since 1924. It was the oldest and longest-inhabited centre of Maya culture. Stratified deposits have been uncovered going back far beyond the first stone-carved records. Here, in what is known as the *A* group of buildings, a palace was excavated by Mr. Ledyard Smith. This is a type of building in the Old Empire of which very little is known. It was found to consist of four courts surrounded by cell-like structures. The greatest height of the building as it now stands is nearly 50 ft. The north court and main court were excavated and were found to be on different levels and connected by stairways. A number of pyramids were also examined, and were found to contain burial vaults which yielded much valuable pottery.

Advantage was taken of the temporary residence of Dr. S. K. Lothrop in Guatemala to engage him in carrying out a preliminary archæological investigation of the Highlands of that area.

In the collateral studies, to which reference is made in the beginning of the report, Guatemala was on this occasion made the principal centre of activity. Geographical reconnaissances were made by Dr. Wallace W. Atwood, president of Clark University, and Dr. Rollin S. Atwood of the University of Florida, the former undertaking the definition of the physiographic provinces of the Highlands, with special reference to Lake Atitlan and adjoining territory; while Dr. Rollin Atwood made a detailed geographical survey of the region of Chichicastenango.

A medical expedition worked in Yucatan under Dr. George M. Saunders, collecting information upon the various forms of malaria and amœbic dysentery. The prevalence of three types of malaria was demonstrated, as well as an infestation with the amœbæ causing dysentery. The medical expedition to Guatemala under Dr. George G. Shattuck had as its objective a general knowledge of the diseases prevalent in the Highland area and the collection of material for comparison with the low-lying Yucatan Peninsula, especially with reference to the Indian population. In Guatemala, as in Yucatan, the Indians showed an extraordinary resistance to the virus of syphilis.

At Chichen Itzá, Dr. Steggerda made a study of the amount and character of the food of the modern Maya and continued his study of their anthropometry, more especially with respect to growth and genetic study. Dr. Davenport also made an inspection with the view of gauging the possibilities of Yucatan as a field for genetic study.

In the ethnological field Dr. and Mrs. Asael Hanson made a study of the *barrio* of Santa Ana, a part of Merida which has recently undergone great changes towards urbanisation. In linguistics the work was confined to the study of material collected in previous seasons.

Notwithstanding these varied activities, Dr. Kidder notes a number of further problems in topography, geology and climatology which are especially urgent; while in biology, he says, the field "has hardly been scratched".

Alcohol Through the Ages

THE jubilee memorial lecture of the Society of Chemical Industry, which had this title, was given by Dr. E. F. Armstrong and has since been published (*J. Soc. Chem. Ind.*, March 24 and 31). Dr. Armstrong dealt in a very detailed and interesting manner with the production of alcohol and its industrial applications.

The process of distillation was known to the Ancients, though the earliest records of its application for obtaining concentrated alcohol for use by the Arabian doctors of medicine date from the tenth century. Concentrated spirit was prepared by Raymond Lully (born 1235) by dehydration with fused potashes, the name 'alcohol' being used for it by Libavius in 1597. The synthesis of alcohol from ethylene was effected by Henry Hennell in 1827–28. Methylated spirit for manufacturing purposes was legalised in 1855, and in 1902 the use of other suitably denatured alcohol for special purposes was permitted without duty.

In the manufacture of industrial alcohol, fermentation processes still hold the field, but are becoming menaced by the probability of the industrial production of ethanol (ethyl alcohol) from ethylene. The raw material for fermentation (cane sugar molasses, potatoes, sugar beets, maize, grain) varies in different countries. A pure culture of yeast is used and the fermentation is rigidly controlled, the carbon dioxide evolved being utilised in the United States by solidification to form 'dry ice' for refrigeration purposes. Attempts to use sawdust have been made, and in 1930 large quantities of alcohol (about half being used as motor fuel) were made in Sweden from the waste liquors of works producing paper from wood pulp.

Synthetic alcohol (ethanol) can be made from ethylene or from acetylene, but the latter process, once used in Germany, has been abandoned. Ethylene is present in the gas formed in the 'cracking' (thermal decomposition under pressure) of petroleum with the production of petrol. In one process used in the United States, the gas contains 28 per cent of ethylene, with other unsaturated hydrocarbons which can again be cracked to give ethylene with fair yields. Whereas abundant ethylene is available in the United States there is little or none produced at present in this way in Great Britain.

The conversion of ethylene from coke oven gas into alcohol has for some time been carried out in France, the reactions being those used by Hennell:

$$(1)\ C_2H_4 + H_2SO_4 = C_2H_5.HSO_4\ ;$$
$$(2)\ C_2H_5.HSO_4 + H_2O = C_2H_5OH + H_2SO_4,$$

the hydrolysis of the sulphovinic acid being carried out with steam and the diluted sulphuric acid used to make ammonium sulphate with synthetic ammonia. Large quantities of alcohol (4 million gallons up to the end of 1931) have been made from ethylene in the United States at a conversion cost, probably, of 1*s*. per gallon.

Another possible, but still uneconomic, process starts with water gas, containing carbon monoxide and hydrogen. In presence of a catalyst under high pressure, methyl alcohol (methanol) is the normal product:

$$CO + 2H_2 = CH_3OH,$$

but by using a special catalyst, some ethanol is also produced.

In considering the industrial applications of ethanol, Dr. Armstrong referred to its use as a motor fuel in conjunction with petrol, and practically every country has provided by legislation for the production of this fuel. The manufacture of power alcohol is comparatively neglected only in the British Empire, except Southern Rhodesia, Natal and Queensland. The production of absolute alcohol by direct distillation was made possible by the researches of Sidney Young, but these were neglected for some years; the process is now largely used in France and the United States by concerns which have extensive patent rights. Many foreign governments are making the use of alcohol compulsory in order to save money from being spent abroad on petroleum products. The London General Omnibus Co., Ltd. has made extensive trials with mixtures of benzol and alcohol, and the use of alcohol fuels has long passed the experimental stage. The use of alcohol would provide a market for surplus agricultural products. Ether, aldehyde, acetone and acetic acid are all produced from alcohol on the technical scale.

International Commission for the Polar Year, 1932–33

THE International Commission for the Second Polar Year held its third meeting in Copenhagen on May 15–20, under the presidency of Dr. D. la Cour. Representatives from Denmark, Norway, Sweden, Finland, Germany, France, Italy, Holland, Great Britain (Dr. Simpson and Prof. S. Chapman), the Department for Terrestrial Magnetism of the Carnegie Institution of Washington and the U.S.A. Coast and Geodetic Survey attended. No representative from the U.S.S.R., which is taking a large part in the work of the Polar Year, was able to attend.

The report of the president showed that the great enterprise of the Polar Year is being very successful, and that the present unsettled conditions of the world are not having the adverse effects which one feared. At least forty stations north of latitude 55°, of which thirteen are north of latitude 70°, are recording the earth's magnetic field, most of which are using the remarkable quick run magnetographs designed by Dr. la Cour in addition to the more usual self-recording instruments. Three new magnetic stations have been established in the southern hemisphere, at Elisabethville by Belgium, at Cape Town by the University of Cape Town and at Magellanes by Chile, but the work in the southern hemisphere is somewhat disappointingly small.

All the magnetic stations are also taking meteorological observations and a large number of established meteorological stations have augmented their normal observations. The aurora is being studied in greater detail than it has ever been before. The auroral atlas prepared by Prof. C. Størmer has played a large part in the organisation of auroral work and with its help the observations are being made in a systematic manner which will greatly facilitate the discussion of the results. Simultaneous photographs of the aurora from observing points twenty or more miles apart, for the accurate determination of the position of the aurora in the atmosphere, are being made at several stations, amongst which the British station at Fort Rae is one of the most successful, more than 4,000 pairs of simultaneous exposures having already been obtained there.

The investigation of the temperature of the high atmosphere has been greatly facilitated by the use of *radio-sondes*, instruments which emit radio-signals while being carried on free balloons, from which the temperature at each height can be determined. More than two hundred such instruments have been supplied and brought into use at the different observing stations.

For the first time, explosions are being organised in high latitudes, in order to investigate the travel of sound waves through the upper atmosphere under polar conditions. These observations give information about the temperature conditions at much greater heights—40 km. or more—than can be reached by instruments carried on balloons. A grant of 40,000 dollars by the Rockefeller Trust for the purchase of magnetic instruments and *radio-sondes* and the training of observers in their use has been of the greatest value; without this grant it would have been impossible to make observations in many parts of the world, and the investigations of the earth's magnetic field and of the temperature of the upper atmosphere would have been much less complete than they will be now.

The International Union of Scientific Radio-Telegraphy has organised an intense study of the ionosphere during the Polar Year, and the reports of the work of the British station at Tromsö is of outstanding interest and importance, a constant record being obtained of the height and intensity of the reflecting layers.

Without going into further detail, it will be clear that the scientific work during the Polar Year will be of immense value for the solution of many problems of geophysics.

The main work of the Commission was concerned with making plans for the early publication of the results obtained during the Polar Year and their ultimate discussion. The actual working up and publication of the observations must be undertaken by the various countries which have been responsible for making them; but the Commission feels it essential that there should be some central body to direct and facilitate the discussion of the results. For example, it is highly desirable that copies of all the magnetic registrations, taken throughout the world during the Polar Year, should be available at some central place for the convenience of investigators; that a list or index of all the observations made during the Polar Year should be prepared and published so that workers on any problem may know what data are available and where they can be found. The Commission considers that the best way to obtain this end would be to continue its functions after the end of the Polar Year and a resolution to this effect was passed.

The prosecution of the work of organising the discussion of the results will involve considerable expense. As no funds at present exist for such a purpose, the Commission could only express the hope that the necessary money will be made available.

In all, the Commission passed nineteen resolutions and there can be no doubt that very valuable organising work was accomplished.

The King of Denmark received the members of the Commission and expressed his great interest in the work of the Polar Year.

University and Educational Intelligence

CAMBRIDGE.—Dr. R. O. Redman, of St. John's College, has been appointed University lecturer in the Department of Astrophysics and Mr. J. A. Ratcliffe, of Sidney Sussex College, University lecturer in the Department of Physics. Dr. N. Feather, of Trinity College, and Mr. P. I. Dee, of Sidney Sussex College, have been appointed University demonstrators in the Department of Physics.

Candidates for the Michael Foster studentship in physiology are requested to send in their applications, with a statement of the course of research they propose to undertake, to Prof. J. Barcroft, Physiology School, before the end of June. The student receives the annual value of the fund (about £100) and may be re-elected for a second year.

Under the will of Mr. Arthur Marmaduke Shield, who died in 1922, a considerable sum of money was left to the Medical School for the foundation of a scholarship in human anatomy and for the general purposes of the School. A report of the Faculty Board of Medicine has recommended the foundation of the studentship and that the remainder of the bequest should be devoted to the foundation of a readership in pharmacology to be called the Shield readership in pharmacology. The Board wishes to offer the directorship of the sub-Department involved to Prof. E. Mellanby, professor of pharmacology in the University of Sheffield, and, in view of his distinction and present position, it seems appropriate that he should be given a personal professorship which will terminate with his tenure of the office.

DURHAM.—A new lectureship has been added to the Department of Geology, to which Miss Doris L. Reynolds has been appointed. Miss Reynolds was formerly on the staffs of the Queen's University, Belfast, of Bedford College, London, and of University College, London; and her published studies of the sedimentary and igneous rocks of the north of Ireland are well known to petrologists.

LONDON.—The title of professor of philosophy in the University has been conferred on Dr. L. S. Stebbing, in respect of the post held by her at Bedford College.

THE British Government has decided to participate in the management of the International Bureau of Technical Education, and Mr. A. Abbott, formerly chief inspector of technical education, has been nominated as its representative on the Administrative Council and Mr. E. G. Savage, chief inspector of technical education, as correspondent with the Bureau. The address of the Bureau is: 2, Place de la Bourse, Paris, 2e.

THE eighth Summer School organised by the British Social Hygiene Council will be held at St. Hugh's College, Oxford, on July 27–August 3. The study programme includes four lectures in biology by Mr. D. Ward Cutler and Dr. N. J. T. M. Needham, five in psychology by Prof. A. E. Heath and Dr. William Brown, five in anthropology by Prof. R. Firth and Miss Monica Hunter and three in physiology by Dr. Agnes Scott. Other lectures and discussions will deal with prostitution, the unemployed adolescent, problems arising in residential institutions for young people and developments in colonial education. The courses of lectures should prove of special interest to teachers. Further information can be obtained from the Secretary, British Social Hygiene Council, Carteret House, Carteret Street, S.W.1.

APPLICATIONS are invited for the following scholarships administered by the Council of the Institution of Electrical Engineers, of which awards will be made this year: Duddell Scholarship, value £150 per annum, tenable for three years, open to British subjects less than nineteen years of age on July 1, 1933, who wish to take up a whole-time day course in electrical engineering; Ferranti Scholarship, value £250 per annum, tenable for two years, open to British subjects less than twenty-six years of age on July 1, 1933, who are students or graduates of the Institution and desire to carry out whole-time research or post-graduate work; Swan Memorial Scholarship, value £120, for one year, open to British subjects less than twenty-seven years of age on July 1, 1933, who desire to carry out whole-time research or post-graduate work; Silvanus Thompson Scholarship, value £100 per annum and tuition fees, tenable for two years, for works employees; open to British subjects less than twenty-two years of age on July 1, 1933. The successful candidate will be required to take up a whole-time day course in electrical engineering at an approved university or technical college. Inquiries for full particulars and nomination forms (specifically mentioning the name of the scholarship) should be addressed to the Secretary of the Institution, Savoy Place, London, W.C.2.

A CASE for a "Colonial Educational Conference" was made out by Sir George Maxwell, formerly Chief Secretary, Federated Malay States, in a speech made on April 11 at a meeting of the Educational Circle, Royal Empire Society. The importance in colonial administration of paying due regard to indigenous languages, customs and traditions and the view that the language is "the most adequate exponent of the soul of a people" have been often stressed in recent years, notably by the Phelps-Stokes African Commission of 1924 and in memoranda issued in 1927 and 1930 by the Colonial Office Educational Advisory Committee but, said Sir George Maxwell, "Memoranda are not enough". The primary concern of the suggested conference, as of the educational conference of the French Colonial Exhibition of 1931, would be the adaptation of education to the needs of the colonies and it would deal with such matters as: a linguistic educational survey, textbooks, vernacular training schools for teachers, vernacular trade and artisan schools, extent of demand for higher schools and a university; and the power of the colony to assimilate the product. On some of these, light will perhaps be thrown by the series of special lectures to be given at the summer school organised by the British Social Hygiene Council to be held at Oxford on July 2–August 3, on the work of colonial administrators with special reference to the educational aspect. This same problem of the adaptation of education to the needs of a community with a cultural heritage radically different from western civilisation is dealt with at some length in "The House of the People", an account of Mexico's new "schools of action" published by the United States Government Printing Office, Washington (pp. 73, price 10 cents).

Calendar of Nature Topics

South-West Monsoon in India

From November to April the prevailing winds over India blow from the north-east, but during April the direction is reversed and from May to October the winds blow mainly from west in the Arabian Sea and from south in the Bay of Bengal. Among sailors these alternating winds are known as the north-east and south-west monsoons, from an Arabic word meaning seasons. In India, however, the 'monsoon' means rather the annual rains which fall during the period of the south-westerly winds. The latter begin in May, but in this month the amount of moisture in the air is only sufficient to cause scattered thunderstorms. The real monsoon rains begin in June, when powerful streams of air sweep across India from the west on the west coast of the Deccan and from the south in Bengal. Each of these currents has a well marked 'front', which brings the first heavy rains, usually with thunder. The arrival of this front is the 'burst' of the monsoon, which is often heralded by a weak cyclonic depression in the Arabian Sea or Bay of Bengal. The burst of the monsoon occurs early in June on the west coast and on about June 15 in Bengal; normally by the end of June the monsoon is established over the whole of India.

Spring in Northern Europe

In temperate countries the change from winter to summer takes place gradually and often fitfully through a much-varying spring. In higher European latitudes, within the line of the Arctic Circle, the transition is more abrupt and produces startling changes in the countryside. There is a sudden upheaval in early June and, within a few days, the hillsides, previously snow-clad, stream with rushing torrents. Wide patches of earth appear and grow rapidly green. Alpine and other flowering plants follow quickly in profusion, and the sunlit landscape glows with colour. Millais (1919) has recorded that on the north coast of Norway no birds were seen before May 25 except resident ravens and magpies together with various gulls. During the next ten days the first spring arrivals appeared—flocks of snow buntings, redwings, fieldfares, shore larks, and the Greenland wheatear. Soon after the beginning of the ice break in the first week of June, several pairs of long-tailed duck and a pair of red-throated divers were noted. The advent of migrants continued throughout June, until the dotterels, buntings and other late-comers reached summer quarters. On June 6, 1916, Millais witnessed, near Hammerfest, the courtship of the bluethroat. A female was joined by two brilliant males, whose gorgeous throats shone like jewels in the sun. They went through a leaping courtship somewhat similar to the courting behaviour of the common redbreast.

Spawning-Time of the Sturgeon, and the Need for Protection

Formerly the rivers of Poland were famous for the abundance of their sturgeon (*Accipenser sturio*), and of these perhaps the most famous was the Vistula, where a quarter of a century ago large catches were made. Now the numbers have fallen seriously: on the lower Vistula, in Pomerania, the years 1929–32 yielded 65 individuals, the middle regions during

1925–32, 36. The weight percentages caught in different months were :—April 14 per cent, May 37, June 18, August 2, September 2 ; which means that already in April sturgeon are present abundantly in the Vistula and that in August the migration is over. The heaviest individuals appear in April and May, and after June and July the weight suddenly falls, an indication that the latter are the spawning months, since the weight of roe makes up about 20 per cent of the total body weight. The actual spawning grounds in the Vistula have never been discovered.

Now the only area in which a close season is enforced is Pomerania, and there the close season runs from July 15 until August 31 ; so that during the very time when the river ought to be left undisturbed for spawning, fish are liable to be caught. The close season should be extended in area, and also in time to cover the spawning period, say from June 1 to the present closing date. Although destruction of sturgeon for food has had something to do with the growing scarcity of the species, it must not be forgotten that still more is its disappearance due to the pollution of the rivers by the refuse of industrial and human centres. (Wlodzimerz Kulmatycki, in *Ochrona Przyrody*, Warsaw, 12, 8 ; 1932.)

The Spring Flush

Pastures are now approaching the peak of their productivity in England and the skill of the grazier is shown in the most economical conversion of the plentiful growth of grass into a saleable form. The problem has always been recognised as a difficult one, namely, the adjustment of the balance between the interests of the pasture and the grazing stock. Writing of the utilisation of grazing land, Arthur Young says : "There are two opinions directly contrary to each other : first it is asserted by one set of graziers, that, let the grass to be fed consist of ever so many acres, that the cattle should have it all at once. Secondly the other set advance that large fields of fifty, eighty or an hundred acres should be divided, that the farmers may change his stock from one to another and give the grass fresh and fresh".

The difficulty of putting these rival theories to the test seemed insuperable to Arthur Young, on the ground of soil variation and individuality in the grazing stock. Only recently, more than a century after the above was written, are scientific methods of the evaluation of herbage by their botanical composition and the performance of grazing stock being worked out. The difficulties are still there, but modern technique in the field, and the treatment of the data by statistical methods, enables valid conclusions to be drawn from data which present the high degree of variability associated with living material. New aspects of the utilisation of grass land are continually coming to light, and no crop is at present so much in favour for scientific research.

The outstanding feeding value of young grass, the superior qualities of selected strains of the native grasses and clovers, and the extraordinary influence which the grazing animal can exert on the direction of development of a pasture, are all recently established points of first rate importance in grass land management. Pasture management can never be a rule of thumb operation but the time is rapidly approaching when graziers will have a body of well-established principles at their command, in place of the rival opinions no less tenaciously held now than in the time of early writers.

Societies and Academies

LONDON

Physical Society, April 7. A. H. BLATCHFORD : The diffraction of X-rays by liquid sulphur. The X-ray diffraction effects given by liquid sulphur at various temperatures between 130° C. and 260° C. indicate an unstable grouping of atoms of sulphur which becomes less pronounced with increased temperature, and changes in form gradually up to 220° C., when there is a sudden alteration corresponding to the change from the form S_λ to S_μ. Raman and Ramanathan's theory of X-ray scattering by liquids is applicable to some extent at temperatures near the melting-point. E. GWYNNE JONES : The hyperfine structure of perturbed series. Rules governing such effects are derived. It is found that these rules are not analogous to those obtained from the analysis of multiplet structures. A. J. BRADLEY and A. H. JAY : Quartz as a standard for accurate lattice-spacing measurements. A test has been made of the use of quartz as a standardising substance for very accurate lattice-spacing determinations. With copper-K_a radiation it gives a very good photograph with many sharp K_a doublets, which may be measured with accuracy. A redetermination of the axial ratio from an X-ray powder photograph gave $c/a = 1{\cdot}10002 \pm 0{\cdot}00004$, and this value was confirmed by X-ray measurements on several other crystals. Assuming Bergqvist's value for d_{100} (4246·02 X units) it was found that $a = 4902{\cdot}9$ x., $c = 5393{\cdot}3$ x. The values of d_{100} at 18° C. for different specimens all lay between $4245{\cdot}9_5$ and $4246{\cdot}3_0$. L. H. MARTIN and K. C. LANG : The thermal conductivity of water. The parallel-plate method was used over the range 7°–60° C., the apparatus being especially designed to cope with the difficulties which arise in the measurement of the conductivity of a volatile liquid. Two series of measurements were made, the plates in one apparatus having approximately three times the area of those in the other.

Society of Public Analysts, May 3. S. G. WILLIMOTT : An investigation of solanine poisoning. In two districts of Cyprus there is a practice of eating potato shoots and leaves as vegetables, and last year an epidemic of poisoning was traced to this cause. The amount of solanine found in the green shoots of the Irish potato plants consumed in these cases was more than five times the quantity present in the tubers of the same plants. It was found that the solanine content of potato shoots diminishes as the altitude at which the plant is grown increases. Habitual consumers of potato shoots probably acquire immunity to the alkaloid. F. E. HUMPHREYS and H. PHILLIPS : Examination of leather for the presence of extractable chromium compounds. In view of the fact that cases of dermatitis have been attributed to the wearing of chrome-tanned leather, experiments have been made to ascertain the amounts of chromium compounds which can be extracted from various types of chrome leather, under conditions similar to those which the leather encounters during wear. Chrome leathers suspected of causing dermatitis did not contain a greater quantity of water-extractable chromium than did normal leather, but many chrome leathers might irritate the skin of a person particularly sensitive to chromium compounds. Solutions resembling sweat in composition do not remove much more chromium, either as chromate or trivalent chromium compounds, than does water, although slightly acid solutions tend to extract slightly larger amounts than neutral solutions. W. M. Seaber: Barium as a normal constituent of Brazil nuts. Barium occurs as a normal constituent of Brazil nuts, the amounts found in 14 samples of the shelled nut of different seasons ranging from 0·02 to 0·31 per cent. As a rule, Para nuts contain less than Manaos nuts. Nearly the whole of the barium is in an insoluble form, but a considerable proportion of it can be extracted by 0·15 per cent hydrochloric acid, and with higher concentrations of acid it is practically all dissolved. Herbert Hawley: The phytosteryl acetate test as a routine method for examining butter fats. A method is described in which the sterols are directly extracted from a small amount of butter fat by shaking with chloroform and an alcoholic solution of digitonin, and then converted into acetates the melting point of which is determined. The method will detect 5 per cent of vegetable fat in butter or ghee.

Royal Meteorological Society, May 17. D. Brunt: The adiabatic lapse-rate for dry and saturated air. The equation giving the saturated adiabatic lapse-rate is derived as an energy equation, and a slight approximation makes it possible to reduce this to a form suitable for direct computation. The results obtained are represented graphically. An alternative derivation of the fundamental equation for rising saturated air is given, which, by assuming the principle of entropy from the beginning, reduces the derivation to very brief compass. C. S. Durst: Notes on the variations in the structure of wind over different surfaces. Over the sea, the short-period fluctuations in wind are greater in tropical air than in polar air, although when inversions of any magnitude occur over the sea, smooth-flowing air can persist with higher velocities than over agricultural land. An example is shown of the structure of wind over desert, and the frictional churning of the air due to a town is examined; the effects on temperature are found to be appreciable. C. E. P. Brooks and Theresa M. Hunt: Variations of wind direction in the British Isles since 1341. Regular observations of wind direction began near London in 1667, at Edinburgh in 1731 and at Dublin in 1725, and extend, with gaps in the earlier periods, to the present day. Over nearly the whole series the prevailing wind has blown from about west-south-west, but abnormally frequent easterly winds were recorded during the period 1740–48 in London and Dublin and during the period 1794–1810 in London. The present century has been remarkable for the persistence of south-westerly winds. Before 1667, observations are scanty but Merle's diary shows a dominant wind from west-south-west in the years 1341–43, while there is good evidence that easterly winds were abnormally frequent during the latter half of the sixteenth century.

Leeds

Philosophical and Literary Society, March 3. R. Whiddington and J. E. Taylor: Inelastic scattering of electrons in helium at zero angle. Experiments on electron impacts, energies between 40 and 400 volts, with helium atoms have been carried out, the inelastically scattered electrons at zero angle receiving special attention. It is shown that for the 2^1P excitation: the probability is very approximately a linear function of the energy of the incident electrons between about 40 and 400 volts energy; the probability of excitation falls to zero at an energy somewhat greater than that corresponding to the critical excitation energy; and the excitation probability is definitely lower than that predicted by recent theories. R. Whiddington and T. Emmerson: Scattering of electrons in helium. The experimental and theoretical results so far published indicate that both the inelastic and elastic scattering of slow electrons in helium rise to a maximum for zero scattering angle. Using fine electron beams and narrow slits together with magnetic spectrum analysis and photographic recording, results have been obtained at smaller angles than those hitherto investigated, which show a maximum probability at a small angle with a low probability at zero angle. R. Whiddington and F. C. Poultney: Energy of the beams in electron diffraction. The experiment of G. P. Thomson on the velocities of electrons diffracted by passage through a thin film has been repeated. Greater resolving power is obtained by using 90° deviation, when the circular rings become elliptical but are found to remain symmetrical about the central spot. Consequently it is deduced that the velocities are the same to within 0·30 per cent. No trace of diffracted electrons of energy less than that of the main beam is found. Edmund C. Stoner: Interatomic distances and ferromagnetism. Slater's suggestion as to the variation with interatomic distance of the sign and magnitude of the interaction integral is discussed with reference to the relative values of the interaction in the ferromagnetic elements, the change in volume on magnetisation, the variation of atomic moment in alloys of ferromagnetic elements, and the effect of manganese on the atomic moment in nickel manganese alloys. E. C. Pollard: Law of force between neutron and proton. The increase of the heights of nuclear potential barriers with the increase in atomic number is discussed from the point of view of the content of the nucleus; if a polarisation field is assumed between neutron and proton, the experimental figures permit the calculation of the 'polarisibility' of the neutron. This is done. A. W. Foster: Some measurements of the thermoelectric powers of nickel and nickel-chromium alloys in the neighbourhood of their Curie points. The thermoelectric powers of some nickel-chromium alloys have been accurately measured between 100° C. and 450° C. and the destructive effect of small amounts of chromium on the change at the Curie point in nickel confirmed. J. Grainger and Rachel M. Heafford: Some effects of the ordinary tobacco mosaic upon the developmental anatomy of the host plant. Many virus diseases cause a mottling of yellow and dark green areas to appear upon a leaf. The anatomy of these several areas has been studied by many workers who have examined cross sections of the leaf. A recent paper by the authors (*Proc. Leeds Phil. Soc.*, 2, No. 9, 1933), describes the anatomy as revealed by examination in planes parallel to the surface, and also shows the various stages of development of mosaic diseased and healthy leaves. The presence of the virus has the general effect of slowing down the rate of vacuolation of leaf tissues, but it also causes irregularities to appear. The hypothesis is advanced that the anatomical features associated with light green and dark green areas of a diseased leaf can be explained by different relative rates of vacuolation in the upper epidermis, the palisade, the spongy parenchyma and the lower epidermis.

PARIS

Academy of Sciences, April 18 (*C.R.*, 196, 1153–1176). M. GIGNOUX and L. MORET: The prolongation in Haute-Savoie and in Switzerland of the structural units of the Dauphiny Alps. D. VAN DANTZIG: The fundamental group of compact abstract groups. SAINTILLAN: Forces of inertia of a system and a carrying along movement. R. TREMBLOT: A variable star with eclipses of short period. The star *BD.* 10·838 (Henry Draper Catalogue, *H.D.* 26909) has been recently shown by C. Hoffmeister to be a variable with very short period. The author's observations from January until March, 1933, confirm this and suggest that the variability is due to two stars and not to one star rotating on itself. MME. RÉCHID: Study of the thermal decomposition of ammonium phosphate. MLLES. M. MONTAGNE and G. ROUSSEAU: The preparation of the anils of fatty ketones. HENRI LAGATU and LOUIS MAUME: The comparative composition, in the vine, of homologous leaves taken respectively from stems carrying fruit and stems deprived of their grapes. The leaves from stems carrying grapes are poorer in lime, nitrogen and potash but richer in phosphoric acid than the homologous leaves from sterile branches. A. MAGNAN and A. SAINTE-LAGUË: Analysis of the 'hovering' of the *Volucella*. E. FOURNEAU, M. and MME. J. TREFOUËL, D. BOVET and PIERRE KOETSCHET: Chemicotherapy of infections with *Trypanosoma congolense*. The selective action of polyarsenical organic compounds.

CRACOW

Polish Academy of Science and Letters, Jan. 9. L. CHWISTEK, W. HETPER and J. HERZBERG: (1) The fundamentals of rational metamathematics. (2) Remarks on the fundamentals of rational metamathematics. M. JEZEWSKI and J. KAMECKI: The dielectric constants of aqueous electrolytes. The dielectric constants of solutions of various electrolytes have been measured at concentrations varying from zero to 0·01 *N*. K. DZIEWOŃSKI and L. STERNBACH: The reactions of α-naphthylamine with benzoyl chloride. MLLE. J. ACKERMANN: The innervation of the skin of *Amblystoma mexicanum*. Z. KOLODZIEJSKI: The transplantation of young larvæ of axolotl on adult animals. L. W. WISNIEWSKI: Remarks on the systematics of the family of Coitocæcidæ. T. VETULANI: Researches on the types of Arab horses raised in Turkey.

GENEVA

Society of Physics and Natural History, Feb. 16. F. CHODAT and M. JUNQUERA: The reduction of methylene blue by an *Endomyces* at the expense of its endocellular hydrogen donators. The authors study the variations of the reducing activity of *Endomyces Chodati* in the system: methylene blue (acceptor), living yeast (ferment), in the absence of an extra-cellular hydrogen donator (Thunberg's technique, MacIlvaine's buffer mixture, temperature, 40° C.). The optimum conditions of *p*H, and of the age of the organisms are described. α-Monobromacetic acid, even when added in high concentrations, is without effect on the enzymatic process. M. GYSIN: Petrographic researches in the Haut-Katanga. (2) The formations of the Kundelungu. In the south-east part of the Haut-Katanga, the Kundelungu is represented from bottom to top by a schisto-grit dolomitic and clay conglomerate (tillite), by limestones and dolomite massifs, dolomitic grits with a little felspar and clay, by lustrous schists sometimes containing grit and by felspathic and dolomitic grits passing to quartzites. The author gives the correlations between these formations and those recognised in northern Rhodesia and in the cupriferous district of the Katanga. He then describes the petrographic constitution of these different rocks. A. LOMBARD: The Virgulian and the stratigraphy of the Portlandian of the Col du Marchairuz region. The Virgulian in the neighbourhood of the Col du Marchairuz and the Monts de Bière (Vaudois Jura) has been described by various geologists. Completing these data, the author demonstrates that this sub-stage is reduced to zero to the south-west of the Marchairuz. It is then impossible to distinguish the lower Portlandian from the upper Kimmeridgian. The upper Portlandian is characterised by marly limestones, important dolomitic levels and cargneules. The latter increase in thickness from north-east to south-west. The dolomitic layers diminish. H. PAILLARD and R. DUCKERT: Researches on the catalytic oxidation of acenaphthene. The authors have studied the oxidation of acenaphthene in solution in various solvents by the action of compressed oxygen and in the presence of catalysts capable of giving oxides of nitrogen. Under these conditions the only important oxidation product is naphthalic acid. H. PAILLARD and P. FAVARGER. Researches on the chlorination of acenaphthene. The authors have studied the action of chlorine on acenaphthene and the conditions necessary for obtaining a good yield of 5-chloroacenaphthene. A. PERIER: The influence, in a homogeneous ethnic group, of the variation of the cephalic index on that of the alveolo-palatinal and superior facial indices. The superior facial and alveolo-palatal indices show no correlation with variation of the cephalic index. Hence their relative stability, a disharmony inasmuch as the most brachycephalic skulls, are, proportionally, the most leptene and the most leptostaphyline. G. TIERCY: The respective phases of minimum ionisation and light minimum in the Cepheids. The author attempts to show how the combined effect of the curve of radial velocities, of that of light and of the theory of radiating equilibrium affords an explanation of the fact that the minimum ionisation phase precedes the light minimum.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Wednesday, June 7

FOLK-LORE SOCIETY, at 8—(at University College, Gower Street, W.C.1).—Mrs. E. S. Drower: "Mandean Magic, White and Black". (*Discussion*).

Thursday, June 8

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, at 2.—Sir George Buchanan: "International Hygiene" (succeeding lecture on June 9).*

UNIVERSITY COLLEGE, LONDON, at 2.30.—Sir Flinders Petrie: "Egyptian Links with the Past" (to be repeated on June 10 at 3, and June 13 at 5.30).*

ROYAL COLLEGE OF PHYSICIANS OF LONDON—(Croonian Lectures).—Prof. E. Mellanby: "Nutrition and Disease—the Interaction of Clinical and Experimental Investigations" (succeeding lectures on June 13 and 15).

Friday, June 9

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, at 2.—F. Radcliffe: "Factory Medical Work".*

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, at 5.—N. H. Mummery: "The Practice of Industrial Medicine".*

ANNUAL CONGRESS OF THE SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES, June 7–10. Prof. E. J. Salisbury—president.

Co-operative Industrial Research

THE Committee on New Industrial Development last year considered a proposal for the creation of a new national research organisation particularly to assist in the industrial development of ideas, inventions, or processes likely otherwise to remain undeveloped in Great Britain, and thus to close what was alleged to be a definite gap in our existing organisation of research. With this proposal the Committee did not agree and the opinion was recorded that the proposed organisation, the suggested functions of which would go far beyond the organising and undertaking of research, would be superfluous and more likely to cause confusion than to forward the cause of scientific research in industry. Although the Committee's reasons for rejecting this proposal were soundly and convincingly argued, the report did not suggest that the organisation of research in Great Britain was by any means perfected and the Committee indicated indeed points at which much wider use might be made of existing facilities.

On the other hand, a paper like that read a little while ago by Sir Harold Hartley, when he reviewed scientific research on the London Midland and Scottish Railway, gives such an impressive picture of the possibilities in co-operative research already existing in Great Britain that an optimistic view of their resources is easily engendered. It is clear, however, from the reports of the Advisory Council which directs the work of the Department of Scientific and Industrial Research that, while the framework may exist, it has not yet been developed to an extent commensurate with either national or industrial needs. Because the existing facilities are not being adequately used, dangerous gaps do in fact exist between pure science and manufacture, and certain industries are a long way from considering seriously how scientific knowledge can be utilised in their processes. Only in one or two spheres has the Department as yet been able to survey national resources as a whole and to endeavour to provide a basis upon which production and consumption could be planned as a scientific whole, in some such way as was advocated by Sir Arthur Salter at McGill University recently. The development of new industries based on a full knowledge of scientific resources and an economic scientific cooperation with other countries might well build a new industrial Britain.

If, however, one of the most important steps to be taken in closing this gap is the education of industry to appreciate the contribution which science can render to its everyday needs, there are other directions too in which action seems to be called for. To one of these Dr. A. J. V. Underwood and Prof. W. E. Gibbs recently directed attention in a letter to the *Times*, and Dr. Underwood has since elaborated his ideas in an article entitled "Some Thoughts on Industrial Research" which appeared in the *Chemical Trade Journal* on March 17. Apart from the fundamental scientific research which in the main is the field of the universities, and the industrial research which is concerned with the improvement of processes or the development of new products, Dr. Underwood directs attention to the position in Great Britain of industries too small to support a research association, and to the facilities which exist for research on problems which in scope are far beyond the limits of a single industry.

Dr. Underwood advances no evidence to show that the requirements of the small industry could not equally well be met by utilising the resources, for example, of the National Physical Laboratory or the National Chemical Laboratory, and a proposal to establish an institute for the benefit of industries or firms too small or backward to provide for their own research resources cannot command much support at the best of times. As example of his second point, Dr. Underwood cites the unit processes of chemical engineering, such as drying, filtration, evaporation, mixing, grinding, which are basic in many industries and differ in their application mainly in the materials handled, and here he is on much firmer ground.

Dr. Underwood urges that research in such fields should be conducted on as wide a basis as possible, so that any developments and advances would be available to all the industries concerned and progress in one industry be reflected in other entirely non-competitive industries. On this ground he advocates the establishment of an Institute for Industrial Research on the lines of the Mellon Institute in the United States, and claims that in such fields the proposed institute would offer great advantages in efficiency, economy and the interchange and discussion of ideas among scientific workers. Particularly he stresses the desirability of establishing it in close association with a university, and the value of the institute to firms too small to justify the formation of a separate research association.

It is thus clear that the Institute Dr. Underwood has in mind is something quite distinct from the proposal considered last year by the Committee on New Industrial Development. On the other hand, the Department of Scientific and Industrial Research, as indicated in its current report, has endeavoured with some success to foster fundamental research of this type in fields of common interest to a number of industries. Even in the particular field of chemical engineering used by Dr. Underwood as example, much useful co-operative work is already being done, in which the Department of Scientific and Industrial Research itself is prominent. Examples of this are afforded by the activities of the National Physical Laboratory or of the Non-Ferrous Metal Industries, the British Refractories, and the British Electrical and Allied Industries Research Associations among the research associations, or in the work of the various research boards such as those concerned with fuel problems, building research, radio research, lubrication, etc. There is already in existence a good deal of machinery for co-operative industrial research which might with advantage be more extensively used particularly in regard to exchange of information on non-competitive matters. Organisations like the Association of British Chemical Manufacturers and the British Standards Institution in their work on industrial safety and standardisation of practice are also assisting in the development of habits of co-operation and encouraging the exchange of information on common problems.

Nevertheless, it is difficult to resist the feeling that Dr. Underwood has put his finger on a weak spot in our national structure, whether or not it is desirable to create a fresh organisation or institute to meet the needs. The development of one or more of our schools of chemical engineering to undertake work on such fundamental problems might well prove a more satisfactory alternative and one consistent alike with the existing structure of our national research organisation and with the relations between academic and industrial research which exist in other fields. Obviously such development can only be satisfactorily secured if it is planned in relation to national and not merely sectional or local demands, and success will depend on the enlistment of adequate industrial as well as Government support.

The advantages which Dr. Underwood stresses for his scheme in regard to exchange of ideas and discussion among scientific workers, the more efficient utilisation of expensive equipment, and the more effective training of recruits for this particular field are too important to be lightly dismissed. They are points which find an essential place in any definite policy or scheme for scientific and industrial research planned in relation to the national resources and needs as a whole. Whether these needs to which Dr. Underwood directs attention are met within the framework of our existing organisation, or whether it proves necessary to create a new institute for the purpose, a much more adequate conception of the place of research in the organisation and development of our national and industrial resources will be demanded of industry as a whole as well as of Government departments. Industry must learn, too, to relinquish the obsolete ideas of trade secrecy, and to co-operate as fully and wholeheartedly as possible in the exchange of information in investigations of those many problems which are common to divers industries and indeed to many departments of our national or municipal life. Already there are signs that the idea of service is permeating large scale industry to a remarkable extent and the growth of this spirit affords the surest foundations on which not only to build an adequate national structure for scientific and industrial research but also to secure, both within industry and without, that fellowship and understanding between the worker in pure and applied science which is the surest passport to success.

Astrolabes

The Astrolabes of the World: based upon the Series of Instruments in the Lewis Evans Collection in the Old Ashmolean Museum at Oxford, with Notes on Astrolabes in the Collections of the British Museum, Science Museum, Sir J. Findlay, Mr. S. V. Hoffman, the Mensing Collection, and in other Public and Private Collections. By Dr. Robert T. Gunther. Vol. 1: *The Eastern Astrolabes.* Pp. xvii + 304 + 68 plates. Vol. 2: *The Western Astrolabes.* Pp. viii + 305 – 609 + plates 69–153. (Oxford: Printed at the University Press, 1932.) £10 10*s*. net.

THE Oxford University Press has produced for Dr. Gunther two sumptuous volumes. The binding is elegant, the paper is good, the print, except in the facsimile of Morley's description of a planispheric astrolabe, is clear, and the numerous photographic plates are exceedingly beautiful; these number no less than 153 in addition to 217 figures. There could scarcely be a book better fitted to lie as an ornament on a library table, and there could scarcely be a book better fitted to be left unread. Wherever I have been able to check the author, I have found him careless both in his statements and in the correction of the press. Of the latter fault there are two examples in the preface. Not all the erudition of the University Press readers has saved Dr. Gunther from the solecism *De Astrolabii Canones*, repeated not indeed in all, but unhappily in most of the passages where the name of Robertus Anglicus's work occurs. In the same sentence the subject 'pages' is followed by the singular 'is'. The Table of Contents not only repeats the incorrect title of Robertus Anglicus's work, but also gives us 'Severas Sabokt' for Severus Sabokt, and in five places it substitutes 'Bleau' for Blaeu. After fifty pages of a mechanical facsimile of Morley's work, the author's own qualities are displayed again. On p. 53 the very name of the instrument to which the volume is devoted is given as *ἀστρολάβον* instead of *ἀστρόλαβος*. On p. 59 Prof. Jenkin has become Prof. Jenkins, the date of his astrolabe being variously given as 1925, 1927, and 1928. Dorotheus of Sidon changes sex and becomes Dorothea. After this one cannot complain of a variation between Philopon, Philoponus, and Philopons.

The errors on the history and literature of the astrolabe are more astonishing. The references to Chaldean fragments, to the object found off Anticythera, and to the early invention of the *arachne* are irrelevant. The author seems to know little of the evidence connecting Ptolemy with the astrolabe and implies that it was among the discoveries codified in the Almagest. Misled by a clerical error on the part of Mr. Dalton, whom he does not cite for his statement, he places Ptolemy in the first century A.D. He argues that "the philosopher who invented the astrolabe", mentioned by Severus Sabokt, must be older than Ptolemy, because the former uses the ancient value of 24° for the obliquity of the ecliptic, whilst Ptolemy adopted 23° 51′. Here he overlooks the fact that, in his treatise on the planisphere, Ptolemy suggests the use of the round quantity, 24°. Our principal authority for the early history of the astrolabe, Synesius, seems to be known to Dr. Gunther only at third hand. At all events he gives a quotation by Mr. Dalton of a quotation by W. S. Crawford from the original. He is in error in supposing that Synesius's gift to

Pæonius was an astrolabe. It was a planispheric star-map. He is also in error in supposing that Synesius claimed to have invented the planispheric astrolabe. He claimed that under the guidance of Hypatia he had perfected the theory of the planisphere. John "Philopon" is dated on p. 59 "about the time of the Great Fire at the Library (A.D. 642)", in spite of all that Gibbon has done to disprove the legend of that fire. Of course Philoponus should have been dated a century earlier. On p. 568, however, Philoponus appears as a Greek author in the reign of the Palæologi who rescued several fragments of Persian and Arabian science by translating them into Greek. Nicephorus Gregoras, a fourteenth century writer on the astrolabe, is dated 758–828.

Dr. Gunther's information about the Renaissance literature is equally unreliable. He prints an imposing bibliography, but does not name his sources. It must contain many books that he has never seen. He states that the early work "De Astrolabio" attributed to Proclus was printed at Venice in 1491. The work in question was certainly by Proclus, but it does not mention the planispheric astrolabe, with which alone Dr. Gunther is concerned. It is Georgius Valla's translation of the sixth chapter of the Hypotyposis, and it was printed not in 1491, but in 1498. 1491, as Harles suspected, and, as Mr. Strickland Gibson has kindly verified for me, is merely a misprint for 1498 in the Bodleian Catalogue of 1674, corrected in all later editions. The work is, in fact, part of the collection of translations by Georgius Valla, which Dr. Gunther notices separately, mixing nominatives and genitives in his own way. He has failed to discover that in the same volume Valla gives under the name of Nicephorus Gregoras not only the actual treatise by that writer, but also an older treatise, attributed in some MSS, I think erroneously, to Ammonius, the Greek text of part of which was edited by Hase under the name of Ægyptius along with the text of Philoponus. He has missed altogether the Basle volume of 1544, in which a composite work appears, consisting partly of chapters translated by Valla from the Hypotyposis of Proclus, partly of a translation by Valla of Philoponus's treatise on the astrolabe, partly of chapters supplied by Valla himself.

On the descriptions of individual astrolabes I have little to say, but I would warn readers to be cautious in accepting identifications of saints and to compare with the plates any erroneous letters or figures attributed to the astrolabes in the text. It is to be hoped that it was not Dr. Gunther who "englished" the inscription given on p. 234, including the phrase, "the consumer of the pertinacy".

The two volumes contain work, however, by others than Dr. Gunther. Morley's most scholarly and most valuable description of a planispheric astrolabe has been noticed already. The late Mr. H. W. Greene contributed a translation of the treatise of Philoponus on the astrolabe. Here we must admire the translator's courage as well as his scholarship. Unfortunately he was unable to discover from Liddell and Scott's Lexicon that ἐξάπλωσις in the first sentence of that work means not 'explanation', but 'projection', making plane, not making plain. Mrs. Margoliouth has given us a combination of her own learning with that of Nau in her translation of Severus Sabokt. She has certainly made her author very clear. There are also two instructive chapters by Theodor Wåhlin on astrolabe clocks and on the availability of the astrolabe for the construction of sundials.

We have also to thank Dr. Gunther for printing a mediæval Latin version of Arzachel's treatise on the Saphea, for reprinting the treatises by Bate and Hermannus Contractus, and for reproducing in facsimile parts of the treatises of Robert Tanner and Robertus Anglicus.

The true history of the origin of the astrolabe is best read in Synesius's epistle to Pæonius. He states, probably on the authority of Hypatia, that Hipparchus, the first to attack the theory of the planisphere, had given a mere sketch of his subject. He attributes to him the insertion of sixteen stars on "the instrument". Ptolemy and his successors were, according to Synesius, content with the practical application of the theory and found these sixteen stars sufficient for time-finding (ὡροσκοπεῖον) at night. Now a planisphere used for finding time at night by means of stars marked on it can scarcely be anything but a planispheric astrolabe. It is natural to suppose that Hipparchus's planisphere, showing the sixteen stars, was also designed for finding the time at night by observing them. But that is not directly stated. Ptolemy himself appears to have mentioned the planispheric astrolabe once only, "Tetrab." iii. 2, where he refers to the time-finding (ὡροσκόπιος) astrolabe as giving a better determination of time than the gnomon or the water-clock. Philoponus informs us that Ptolemy inserted the temporal hours in the planispheric astrolabe. These were the hours in popular use. It should be noted, however, that the planispheric astrolabe is never mentioned by Ptolemy either in the Almagest or, where we should have expected to find it, in his treatise on the planisphere, preserved in a Latin translation of an Arabic translation. There is no mention of it in the published works of Pappus and Theon, or in Proclus. Evidently it was not regarded as an instrument of precision. Heliodorus records an occultation of Saturn, A.D. 503 February 21, where he and Ammonius observed the time of emergence in temporal hours with an astrolabe. This was certainly the planispheric astrolabe. Ammonius, as Philoponus informs us, wrote a treatise on the planispheric astrolabe. Philoponus's own treatise based on this has been mentioned above.

Ammonius, though we know of nothing to connect him with astrology, did in a sense provide the medieval astrologer with all the equipment that he needed. His perpetual ephemeris or "Canonion", called Almanack by the Arabs, gave the places of all planets referred to the ecliptic. The astrolabe gave without computation the reduction from the ecliptic to the horizon, and with the planetary places referred to these two systems of co-ordinates the astrologer could construct his theme. J. K. F.

Central African Volcanoes

Geological Survey of Uganda. Memoir No. 3: *The Volcanic Area of Bufumbira.* Part 1: *The Geology of the Volcanic Area of Bufumbira, South-West Uganda; with Notes on the Petrology and Economic Geology.* By A. D. Combe and W. C. Simmons. Pp. xi + 150 + 12 plates. (Entebbe: Government Printer, 1933.) 15*s.*

IN the brief preface to this new volume, one to be placed side by side with the authors' memoir on the Ankole tin, the Director of the Uganda Geological Survey notes the importance of the area described, distinguished by a recent volcanic activity far grander than the lingering remnants that remain to-day, and suggests, as we are seldom reminded when African volcanoes are concerned, the possibility of renewed outbursts. He mentions also the fact that its leucite-bearing lavas represent, perhaps, one of the largest potash reserves in the world. Moreover, gold has been found.

Part 1, now issued, contains the account of the field geology and the geographical studies of Messrs. Combe and Simmons; Part 2, by Prof. Holmes and Dr. Harwood, is promised in about twelve months and will deal with the chemical and theoretical sides involving petrogenesis, a continuation, we may suppose, of their recent work on the Toro volcanics to the north.

Bufumbira, about one-tenth of the entire field, is situated in the extreme south-west of Uganda and is continued under other names into the Belgian Congo and the mandated territory of Ruanda, the whole being frequently referred to as the Mufumbiro Mountains, but in this memoir as Birunga, the Lunya-ruanda word for volcanoes. Nowadays volcanic activity is extinct in British territory, but Nyamlagira and Ninagongo are active in the west and two others erupted lava in 1905 and 1912 respectively.

The geological structure of the area is comparatively simple; the eruptions have forced their way through the slates and quartzites of the Karagwe-Ankolean system, and the interest of the field is bound up in the composition of the lavas, for the content of potash is unusual, though shared to some extent with the Toro area.

Owing to their position athwart the Central African trough between Lakes Kivu and Edward, the Bufumbira flows built a barrier which dammed the streams flowing north along a pre-Rift depression and formed the southern lake. Three smaller lakes similarly came into existence. Eleven types of lava are shown on the geological map, varying from the enstatite-andesites of Sabinyo, the oldest volcano, to more basic successors usually containing olivine, such as the leucite-basalts. Huge flows of leucite-basanite are commonest.

In addition to three major volcanoes, thirty-four smaller cones have been mapped, usually steep-sided, 200–500 ft. high and built of ash and scoria—in other words, explosion vents. Such safety outlets also occur along ridges of ash and breccia corresponding in direction with the regional strike of the steeply dipping beds of the Karagwe-Ankolean system, indicating lines of weakness, an interesting peculiarity.

The comparative youth of the field, for the most part middle or late Pleistocene, has allowed of an exactitude in observation and resulting precision not so easily accomplished, for example, amongst the volcanoes of Kenya, and it is interesting to note that during distinct periods of activity lavas of different appearance and composition may be produced from a given vent, or the reverse; thus leucite-basalt may be succeeded by leucite-basanite, with intervening limburgite, or vice versa. On the other hand, no change may occur during successive eruptions. The authors record that a traverse from Kisenyi on Lake Kivu to Nyamlagira showed the lavas were melilite-leucite-nephelinites, quite different from the Uganda rocks, where melilite is absent and nepheline very rare.

One peculiarity of the area deserves mention as having possibly a bearing on puzzling occurrences elsewhere, namely, the boulder deposits occupying the pass between Sabinyo and Mgahinga, consisting entirely of masses of lava derived from the first, but lying on flows derived from the second.

Sabinyo is without a remnant of a crater and, as remarked, is the oldest volcano of the area. The deposits are 10–25 ft. thick, the boulders 5 ft. and occasionally 10 ft. in diameter and have moved some two and a half miles from their source. Combe, who visited the Java volcanoes, compares the Uganda deposits to the streams of mud, sand and boulders, called 'lahar', which are ejected from the throat of a volcano charged with steam or gases or with the waters of a crater lake or excessive rain. The latter 'wet' type of lahar, which is known to have moved eighteen miles from its source, presents a close similarity to the Uganda occurrences. Connexions between the deposits and deep erosion valleys cut in Sabinyo are noted, but the precise explanation of the means whereby the boulders reached their present position remains undefined.

Gold, together with tin and wolfram, occurs in the north of the area. Development is still in the prospecting stage, but a noteworthy point, perhaps only of academic interest, is that the gold is found in the Karagwe-Ankolean rocks, usually considered the repository of cassiterite and the associated minerals, a fact which the work of Kitson in the Kavirondo country has already suggested to be possible. The metal as found is usually coarse, yet the ultimate source has still to be discovered, and again we may meet with that crucial point of alluvial prospecting in Central Africa, the possible reversal of an earlier drainage.

The authors are to be congratulated on the results of their painstaking observations, the Uganda Geological Survey and its director on the manner in which letterpress, plates and the excellent coloured map have been reproduced.

JOHN PARKINSON.

Public Analysts and the Food Industry

The Society of Public Analysts and other Analytical Chemists. Some Reminiscences of its First Fifty Years, by Bernard Dyer, and A Review of its Activities, by Dr. C. Ainsworth Mitchell. Pp. viii + 278 + 4 plates. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1932.) 12*s*. 6*d*. net.

IT would be difficult to find a greater contrast than exists between the condition of the food industry now and its condition when the Society of Public Analysts was instituted, the history of which up to the time of its jubilee is recorded in this interesting book. Adulteration of the grossest order was then rife: many dealers sought only to make profits, utterly regardless of the quality of their goods or the effect their sophistications might have on the health of those who consumed them. The idea of a merchant or manufacturer employing a chemist to check the purity of supplies or to make suggestions for the improvement of wares or products would have been scouted as an absurdity; and the recently created 'public analysts' were regarded as the natural enemies of the dealer, and looked on with fear and suspicion.

Now, though adulteration is not extinct, and though it has taken on more subtle forms, yet it has greatly diminished in extent. The manufacture and the merchanting of foodstuffs are for a great part in the hands of large and reputable firms, who employ big chemical staffs, for control both of incoming and outgoing goods, and for research with improvement as its aim, and who are banded together into associations, one of the objects of which is to protect the trade against its less scrupulous members; and the public analysts are looked on, by all except those less scrupulous members, as friends and helpers in the task of supplying the public with pure and nutritious food.

This change has come to pass gradually. Many causes have contributed to it; not the least the activities of the public analysts themselves, individually and through their Society; and the history of the process by which it has been brought about is contained in this book. Dr. Dyer's experience as a member of the Society goes back practically to its foundation; and his happy gift of narrative, and the kindly human nature that peeps through his periods, give a fascination to the perusal of the tale, and will make it interesting reading, not only to those professionally or scientifically concerned with analytical chemistry, but also to any reader who takes an intelligent interest in the things that touch and affect our daily life.

It only remains to say, in the short space available, that Dr. Mitchell's chronological summary of the work of the Society, arranged according to subjects, and dealing not only with the composition of foods and with methods for their analysis, but also with the legal aspects of food adulteration, is a most valuable piece of annotated bibliography, and that Miss Elliott's very detailed index makes it very readily available. J. T. Dunn.

Short Reviews

Incunabula of Tannin Chemistry: a Collection of some Early Papers on the Chemistry of the Tannins reproduced in Facsimile and published with Annotations. By M. Nierenstein. Pp. v + 167. (London: Edward Arnold and Co., 1932.) 12*s*. 6*d*. net.

This elegant volume will delight chemists and botanists who are interested in the history of their subjects. Dr. Nierenstein has made the study of tannin chemistry peculiarly his own, and it was a happy inspiration that led him to select and reproduce the early classical articles in this field of research. His facsimiles include two pages of a 1485 "Hortus Sanitatis"; an excerpt from Baptista Porta's "Natural Magic", describing a method of writing upon eggs by means of galls and alum; Piepenbring's paper "Ueber die Säure der Galläpfel", 1786; Davy's article on "Different Methods of obtaining Gallic Acid", 1805; and papers by Pfaff, Biggin and others.

The facsimiles are followed by eight pages of historical, chemical and bibliographical annotations, in which Dr. Nierenstein's erudition is employed to advantage but not paraded. We learn that the earliest scientific data on the chemistry of the tannins were due to Tachenius, who in 1677 expressed the view that the black colour produced on mixing extract of galls with a solution of green vitriol was to be explained by supposing that the galls contained an alkali that "doth suck up the *Acid Spirit* of the *Vitriol*". Gallic acid was discovered in 1787 by Scheele, while the estimation of tannin was first successfully elaborated by Biggin in 1799.

Dr. Nierenstein has a sly poke at those who believe in certain interrelationships between the tannins and the resins, remarking that this error of Bouillon-Lagrange "still survives and has its supporters amongst those who write on the tannins, but have not worked on this subject". We congratulate Dr. Nierenstein upon his handsome contribution to historical chemical literature, and his publishers and patrons for their enterprise in publishing and subsidising it.

Through Wonderlands of the Universe. By R. K. Golikere. Pp. xviii + 400. (Bombay: D. B. Taraporevala, Sons and Co.; London: Kegan Paul and Co., Ltd., 1933.) 6.4 rupees.

Here is a compendium of information dealing with our universe from the world in which we live to the most distant stars. Its author tells us it is "a simple elementary study" but it contains the speculations consequent upon the researches of Jeans, Eddington and Jeffreys to which we would scarcely have applied the term "elementary". Yet so clever a form has been adopted that every part of the book is intelligible both to laymen and to "junior students" of science. Our Norman period is usually headed '1066 A.D.', and here most chapters have headings with some figure in feet or miles. Each such figure is followed by a note on the subject, the most striking and modern facts and thoughts thereon. The land surface thus has a series of 135 height headings and the ocean 46 depths. There is a deliberate lack of order in arrangement of these facts—or a very clever conception of human psychology. It is rather boring to have the depths of oceans reeled off in rotation by a lecturer or printed in a column, but if these are interspersed as here with the maximum depths of fish, corals, sponges, starfishes, submarine cables, etc., about each of which there is a pleasant little story, the facts remain with us.

The author is the devoted pupil of Jeans, who is often quoted and discussed. The last chapter is on Hindu cosmogony and cosmography and this we would like extended, a view with which we are convinced most Hindu readers will agree. It is good to see expositions of the far-reaching conceptions consequent on the researches of science and to have these blended with the more striking phenomena in our planet and its civilisation.

Mr. Golikere is brave and original and hence well deserving of success; he is never dull and this is the best that can be said of any author.

La géologie et les mines de la France d'outremer. Recueil de conférences organisées au Muséum par les soins du Bureau d'Études géologiques et minières coloniales sous le haut patronage de A. Lacroix, et avec le concours de L. Bertrand, F. Blondel, J. Bourcart, A. Demay, M. Dreyfuss, L. Dubertret, P. Fallot, M. Glasser, H. Hubert, Ch. Jacob, L. Joleaud, A. Lacroix et L. Neltner. Pp. viii + 604. (Paris: Société d'Éditions Géographiques, Maritimes et Coloniales, 1932.) 70 francs.

The great mining and metallurgical industries of France recently formed a committee to study the mining possibilities of the French colonial empire. This committee established a Bureau d'Études géologiques et minières coloniales, which, with the collaboration of the French Government, was charged with the training of specialists for the investigation of the mineral deposits of the Empire, and with the education of the French public, especially the official and financial fractions thereof, in regard to the possibilities of their overseas possessions. With this latter end, a series of lectures was given during last winter at the Muséum d'Histoire Naturelle by geologists familiar with the different French colonies. These lectures have been collected in the present work and issued by the Bureau.

The volume is the first general study of this kind dealing with the French possessions. The geology and mineral resources of each colony are set forth in detail and the volume will be of great use to geologists, since a synopsis of this kind has been hitherto exceedingly difficult to make. Those interested in the relative distribution among the nations of the minerals necessary for large-scale modern industry will find in this book food for anxious thought.

Objektive Spektralphotometrie. Von Dr. L. S. Ornstein, Dr. W. J. H. Moll und Dr. H. C. Burger. (Sammlung Vieweg: Tagesfragen aus den Gebieten der Naturwissenschaften und der Technik, Heft 108–109.) Pp. vi + 146. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1932.) 10.80 gold marks.

THIS addition to the well-known "Sammlung Vieweg" monographs is published at a time when considerable attention is being given by spectroscopists to measurements of spectral intensity. It is for this reason, in the first instance, very welcome. The prestige of its authors in this particular field of work gives it at once considerable value. The many workers who are unable, for various reasons, to acquire first-hand experience of the technique of the school founded by Prof. Ornstein at Utrecht cannot do better than study this book. We are here given precisely the kind of information which anyone desirous of undertaking research in this field would wish to possess.

In addition to the principles underlying, and the actual technique of, spectro-photometry with photographic plates, several useful chapters are included. The thermal and the photoelectric methods of measuring radiation are dealt with in some detail. The photographic plate and the factors upon which its blackening depends are treated well. A separate chapter deals with the micro-photometer and its applications. The practical character of this monograph should make it widely appreciated. R. C. J.

Handbuch der Spectroscopie. Von Prof. H. Kayser und Prof. H. Konen. Band 8, Lieferung 1. Pp. iv + 654. (Leipzig: S. Hirzel, 1932.) 67.50 gold marks.

KAYSER'S "Handbuch der Spectroscopie", in particular vols. 5 and 6, have been of inestimable service to generations of spectroscopists. The earlier volumes, owing to the rapid development of the subject, are generally regarded by the modern worker as of historic interest only. There must always be a place of value for a compilation of reliable data such as at the time of publication vols. 5 and 6 represented. Vol. 7 and, now, vol. 8 (both in collaboration with Prof. Konen) are an admirable attempt to bring up to date this aspect of the subject of spectroscopy. The task is a formidable one and criticism of any kind would be ungracious. We could have wished, however, that it might have been possible to make use of energy-level diagrams in presenting the data in suitable cases. A list of the elements dealt with may be of interest to those working in this subject. They are: silver, aluminium, argon, arsenic, gold, boron, barium, beryllium, bismuth, bromine, carbon, calcium, cadmium, cerium, chlorine, cobalt, chromium, cæsium, and copper.

While recognising that a work of this kind cannot be published cheaply, most English workers will probably feel that the price is formidable.
R. C. J.

The Annual Register: a Review of Public Events at Home and Abroad for the Year 1932. Edited by Dr. M. Epstein. Pp. xii + 318 + 180. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1933.) 30*s.* net.

THIS valuable summary of the history of the past year compresses into a few hundred pages the vicissitudes of a troubled period in most countries. There was much to record but the task has been accomplished within the customary space without the exclusion of any movement of importance. As usual, British, Imperial and foreign history occupy about two-thirds of the book. Then follow summaries of literature, art, drama, music, science, finance and law with an obituary and biographical notices. Into fourteen pages is condensed an outline of scientific advances during the year. Among the documents published *in extenso* in the volume are the summary of conclusions of the Imperial Economic Conference at Ottawa in July 1932, and the Note to the United States government on the War Debt in December last.

Introduction to Theoretical Seismology. By Rev. J. B. Macelwane and Rev. F. W. Sohon. Part 2: *Seismometry.* By Rev. F. W. Sohon. Pp. ix + 149. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1932.) 16*s.* 6*d.* net.

THIS useful book is the first account in English of the instrumental side of seismology since that of G. W. Walker. It proceeds by easy stages from the simple pendulum to the complications of modern seismographs, going so far as to explain the difficulties attendant on the second and third order terms in the vertical instruments. Methods of determining epicentres are described, but it is surprising to find no mention of Turner's direction-cosine method of determining epicentral distances.

Muscular Movements of Fishes*

By DR. J. GRAY, F.R.S.

IF a body is moving through water at a constant speed, the body must be constantly supplied with energy. In the case of a fish, the requisite energy is supplied by the muscles and is applied in such a way as to exert a backward thrust on the water, which compensates the resistance exerted by the water on the body of the moving fish.

As observed by the human eye, the motions of various types of fish appear to vary considerably from one species to another. At one extreme is the eel, which, during motion, is characterised by distinct waves of curvature which pass alternately down each side of the body from head to tail. At the other extreme is the mackerel or the trout, which appears to progress by means of transverse strokes of the expanded caudal fin. An examination of successive instantaneous photographs shows, however, that the nature of these two types of movement is essentially the same, for in all cases, waves of curvature pass along the body with increasing amplitude as the hind end of the fish is approached. The only significant differences between the eel and the mackerel are the relatively larger amplitude of the waves towards the anterior end of the eel, and the relatively longer body—with consequently longer length of wave—in the eel as compared with the mackerel. Both the nature and frequency of the waves of muscular curvature vary in different cases.

As recorded by the eye, the movements of a fish are almost invariably movements of one part of the body relative to another—we watch the waves of curvature passing backwards relative to the head of the eel, or we watch the tail of a mackerel sweeping from one side of the body to the other. From a propulsive point of view, however, we are more concerned with the motion of the body relative to the surrounding water, and in order to record such movements it is necessary to employ a camera, and to photograph the fish, against a clearly defined background, at known intervals of time. Observations of this type enable us to record the movements of each part of the body relative to other parts and relative to the surrounding medium.

Records have been made of a number of typical fish, but, owing to the well-defined nature of the muscular waves, attention may be first concentrated on a small glass eel (*Anguilla vulgaris*) which is approximately 7 cm. in length. It is found that each point on the animal's body is travelling forward through the water along a sinusoidal curve the 'pitch' or wave-length of which is the same for all points of the body (namely, 3·2 cm.) but the transverse amplitude of which becomes progressively greater as we select points lying farther away from the head. If we select two adjacent points on the body and plot out their movements relative to the background of the fish, it is seen that each sector of the body is moving with its leading surface inclined at an angle to its own path of motion. The photographic records also show that, relative to the head of the fish, each leading surface is always directed obliquely backwards except at the extreme positions of the displacement.

The leading surface of the fish has therefore two distinct properties: (1) it faces obliquely backwards relative to the head of the fish; and (2) it is moving at an angle to its own direction of motion. These two properties are responsible for the forward propulsion of the fish. So long as the leading surface is moving at an angle with its own path of motion, there will be a pressure exerted at right angles to the surface, and so long as the leading surface is directed obliquely backwards relative to the head of the fish, the pressure will be directed obliquely forwards. The forward component of this pressure tends to drive the fish forwards.

The principle is fundamentally the same as in a screw-propeller or in the blade of a sculling oar during the first part of its stroke. In the screw propeller the leading surfaces of the blades represent surfaces directed obliquely backwards relative to the ship and, when the ship is in motion, they are moving forward at an angle to their own path of motion. In the case of the fish, the propellant surfaces are moving in two dimensions instead of in three—and this is possible by virtue of the elasticity of the body, which enables the leading surface to be suitably reorientated at the end of each transverse cycle.

The surface of a screw and the leading surface of a fish's body resemble each other in that they are always exerting a pressure at right-angles to themselves, although, in the fish, the extent of this pressure varies at different points on the body and at different phases of each transverse movement. The waves which pass down the body of a fish also have their counterpart in the mechanical screw. If the pointed end of a household screw is held vertically downwards and the screw be rotated, it can be seen that the edges of the screw surface appear to move along the side of the screw in a direction which varies with the direction of rotation. If the screw is turned 'in' the ridges appear to move upwards; if the screw is turned 'out' the ridges appear to move downwards. If, however, the screw is free to move in a well-fitted nut, the ridges appear to be stationary when the screw is rotated in either direction. It can be shown fairly simply that the screw will only do work when the 'ridges' appear to move upwards or downwards at a greater rate than that at which the screw itself is moving in an opposite direction. The same facts can be summarised by saying that the screw will only exert a pressure when there is an 'angle of attack' between its leading surface and the direction of the latter's motion; within limits, the greater is this angle of attack the greater is the pressure exerted by the screw. So also in the eel, the surface of the body can only exert a forward thrust when the waves of muscular contraction pass backwards along the body at a greater rate than that at which the fish is moving forwards through the water. When a wave passes down the body of a fish at rest, the angle of attack is, at first, of maximum value and the thrust is correspondingly high—consequently the fish rapidly gathers speed until the angle of attack gives a thrust which is equal to the forces resisting the motion of the whole fish; during this period, there has been a steady reduction in the rate at which the muscular waves are travelling backwards relative to the environment. If the fish, having acquired a uniform speed, increases the velocity at which it transmits the waves along its body, then the angle of attack will again rise. A second period of acceleration of movement will occur until the angle of attack has again fallen to an equilibrium value. For any given speed of transmission of the waves along the body there must be a definite speed of forward propulsion which depends on the form of the fish's body. A series of waves passing down the body of a fish must therefore automatically travel at a greater speed than that at which they propel the fish forwards. Correspondingly, if the direction of the waves is reversed, the fish moves backwards—a phenomenon clearly seen in a large conger eel.

---

* Friday evening discourse before the Royal Institution delivered on April 28.

We may conclude that the whole body of the eel is acting as a propeller by virtue of the fact that the leading surface is always inclined obliquely backwards relative to the head and at an angle to its own path of motion.

If we now consider the movements of a whiting or other typically pelagic fish, certain points of difference are obvious: (1) the length of the body, relative to its cross-section, is much less than in the case of the eel; (2) the hind end of the body tapers relatively abruptly and ends in an expanded caudal fin. When recorded photographically, however, the movements of the body are found to be of the same fundamental type as those of the eel, for in all cases waves of curvature pass alternately down each side of the fish.

In the whiting, the amplitude of these waves remains quite small until the posterior region of the tail is reached, where it increases more abruptly than in the case of the eel. The effect of these waves is such as to maintain the leading surface of the body inclined obliquely backwards relative to the head. A similar orientation is maintained by the leading surface of the caudal fin, and since the area of the fin is considerable, it is of interest to consider how far it plays an essential rôle as a propellant surface. It is well known that fish with badly lacerated caudal fins can swim actively and the observations of Breder show that amputation of the caudal fin of *Scardineus* does not markedly affect the speed of propulsion. This observation has been confirmed by the removal of the caudal fins of the rudd, the perch, and the whiting. For technical reasons it has not been possible to observe the effect of amputation of the caudal fin in fish moving at a high speed, but it seems fairly clear that the 'cruising' speed is not appreciably reduced.

At first sight, these facts suggest that the main propulsive surface of a whiting is provided by the body itself and that the surface of the caudal fin is relatively insignificant. An examination of the photographic records, however, shows that the removal of the caudal fin alters, in a significant manner, the movements of the fish. In the intact fish, we have seen that the leading surface of the body is always directed obliquely backwards. When the caudal fin has been removed, however, this is no longer the case, for the stump of the tail now swings about its base as a relatively rigid structure; as it moves from the extreme position of displacement towards the central position its leading surface is directed obliquely backwards, but as it moves from the central position towards the extreme position of displacement on the other side, the leading surface is directed obliquely forwards.

The difference between the movements of the intact fish and those of one from which the caudal fin has been removed is clearly due to the resistance which the tail fin offers to transverse movement. The fin represents a surface of high resistance lying posteriorly to the region of muscular contraction and it causes the intervening region of the body (which is flexible) to bend into an arc, with the convex surface towards the direction of motion; in other words, the fin causes the posterior region of the body to lag behind all those parts which lie between itself and the point of contraction so that each group of muscles, as it comes into play, is operating on a region of the body which is directed obliquely backwards relative to the head. The effect of the fin is exactly parallel to that produced by attaching a flat plate to the distal end of a steel wire and oscillating the proximal end of the wire through a small angle. Without a flat plate each part of the wire moves in practically the same phase as any other part—but when the plate is present the distal end of the wire lags behind the proximal end. A series of movements is set up which is strikingly similar to the normal movements of a fish's body; without the attached plate, the movements of the wire are comparable to those of a fish from which the tail fin has been removed.

At first sight, it seems strange that a fish can move forwards without a tail fin, for one might imagine that the propulsive effect produced when the tail is directed obliquely backwards would be exactly neutralised by the action of the tail when directed obliquely forwards during the second half of each stroke. It must be remembered, however, that so far we have been considering the movements of the tail relative to the head. When we examine the movements of the tail relative to the water, we see how the fish—without a caudal fin—can propel itself through the water. During the first half of the stroke, the tail is not only directed obliquely backwards but it also sweeps through the water, thereby generating a forward thrust, but at the moment it begins to face obliquely forwards, its motion through the water is checked, for it begins to move against the water which is flowing past the sides of the fish. The tail then begins to act as a rudder, and the position of the tail relative to the head is maintained by a movement of the head end of the fish through the water instead of by a movement of the tail. The two phases of each stroke are thus asymmetrical and the fish is able to progress through the water, although not in the smooth steady manner characteristic of the intact fish.

It is clear that by exerting a mechanical resistance to transverse movement through the water, the caudal fin of the whiting maintains the necessary phase difference between successive regions of the muscular body and tail, and thereby enables the whole of the energy of the muscular contractions to be expended in a smooth symmetrical manner. The question may be asked: Why can an eel or dogfish progress smoothly without the presence of a large caudal fin? The answer is that the function of the caudal fin of a whiting is, in the case of the eel or dogfish, carried out by means of the long flexible body itself. In exactly the same way, well-defined waves can be transmitted along a long flexible wire without the presence of a flat plate attached to the distal end. It is only when the wire is short that a flat plate is essential for maintaining an adequate phase difference between successive regions along its length.

Although the removal of the caudal fin does not substantially reduce the forward rate of movement, it is not legitimate to assume that the propulsive thrust from the fin is negligible in the intact animal, for it has been shown that amputation of the fin induces far-reaching changes in the movements of the remainder of the body relative to the surrounding water. A preliminary attempt to estimate the propulsive effect of the tail fin of the whiting was carried out as follows.

A series of vertical rods was so mounted in a metal frame that each rod moved harmonically with the amplitude characteristic of different levels of a whiting's body; the ends of the rods were then inserted into the body of a dead whiting. By rotating a handle, the body of the fish was forced to transmit a series of waves identical with those seen in the normal living fish, and for a given frequency of waves the velocity of the current produced in a tank of water was determined. The caudal fin was then removed and the current again measured for the same frequency of movement. Although the method of measuring the current was not free from criticism, the results suggest that approximately 40 per cent of the propulsive thrust from a whiting is derived from the caudal fin.

It is of interest to note that just as the propulsive thrust represents the forward component of the pressure of the fin against the water, so the transverse component of this pressure plays its part in adding to the resistance offered by the fin to transverse movements, so that the biological functions of the fin are very clearly linked together, just as is the case with the surface of the body itself. If the area of the body surface is large in comparison to that of the fin, the rôle of the fin may be relatively insignificant as in the eel, but in the pelagic type of fish the posterior region of the muscular tail is comparatively narrow and tends to present a convex surface to the water, whereas the tail fin is relatively large and presents a flat surface to the water. In the latter case the fin probably plays an increasingly important rôle as a propeller, just as it plays an increasingly important rôle by virtue of its resistance. Until a very accurate method is devised for measuring the currents produced by various types of tail fin, it is dangerous to speculate on the effect produced by variations in the shape of the caudal fin.

So far, we have only considered the motion of fish which are swimming in a straight line, but one of the most striking features of a moving fish is its ability to change the direction of its motion. In some cases such changes are effected by movements of the paired fins, but the rapid changes so characteristic of pelagic types are effected by the muscles of the body itself. In all cases a change in the direction of motion has been found to be due to the propagation of a muscular wave along one side of the body, and the fish always turns towards the side along which the wave is travelling. These waves are most conspicuous in the case of the eel, but they can be recorded photographically in other types. We may take as an extreme example the goldfish. As observed by the eye, a goldfish appears to turn by a rapid flexure of the tail towards one side. Actually, however, the tail remains practically stationary in the water until the head end of the fish has almost if not completely finished its turning movement—after which the tail swings through the water towards the opposite side to which the animal turns.

The examination of a number of photographic records has shown that the turning movement of such fish is divisible into two parts: (1) the head moves through the water by using the tail fin as a relatively stationary pivot; (2) the tail moves through the water using the head as a stationary pivot. The effect of the tail fin during the first phase of the movement is simply an exaggeration of its effect during normal swimming, namely, to delay the movements of the hind end of the body whilst movements are occurring farther towards the head. As one might expect, the amputation of the caudal fin exerts a very far-reaching effect on the turning powers of the fish. A normal goldfish can turn through nearly 90° by one flexure of the body—but if the caudal fin be removed, the same turn can only be effected by several flexures. With or without a caudal fin the amplitude of the muscular contractions is practically the same, but in the absence of the caudal fin a muscular contraction on the left side of the body causes both head and tail to move simultaneously to the left of the original axis—in the presence of a caudal fin only the head moves whereas the tail remains stationary. Since the curvature of the body is the same in the two cases, it follows that the angular displacement of the head through the water is greatly reduced by the amputation of the fin. The maximum change in the direction of the fish cannot exceed the initial movement of the head, and this can only be maximal when the posterior end of the body remains undisplaced. Clearly the function of the tail fin is to enable the hind end of the body to act as a fulcrum on which the head turns. As in normal motion, the rôle of the caudal fin is, in the eel or dogfish, carried out by the long flexible body itself.

We have now seen that the caudal fin exerts two forces on a moving fish : (1) it tends to inhibit the transverse movements of the hind end of the body ; (2) it exerts a fraction of the forward propulsive thrust. Both these forces are derived from the pressure exerted on the water at right angles to the surface of the fin. The 'resistant' force is the transverse component of this pressure, and the propulsive thrust is the forward component. The absolute and relative values of these forces remain to be determined.

So far, we have considered the movements of the body without reference to the actual process of contraction of the muscles. The muscle fibres of the trunk and tail all run parallel to the long axis of the body, and they are so controlled that when a fibre on one side of the body is fully contracted, its opposite neighbour on the other side of the body is fully relaxed. Further, it is clear that the fibres along one side of the body do not contract simultaneously but in sequence, beginning with those nearest to the anterior end of the body. Each group of fibres is supplied by motor nerves, and it has been suggested that a muscular wave is the result of the passage of a nervous disturbance down one side of the spinal cord, firing off each group of fibres as it goes. It is difficult, on this view, to account for the very variable speed of transmission of the muscular waves.

There are, on the other hand, a number of facts which suggest that when the muscles (lying on one side of the base of the muscular tail) contract, their energy can be transmitted mechanically along the body of the fish just as such energy can be transmitted along the length of an elastic wire. The energy is transmitted in the form of tension by the stretched skin and muscles of the leading side of the body. If the muscles lying nearer to the tip of the tail are to be usefully employed, they must liberate their energy in phase with that of the mechanical wave. When the mechanical wave reaches any given point it first tends to store energy at that point by bending the body into a convex curve—and then this energy is afterwards liberated as the tension is released. If, therefore, the muscles at any point are to supplement this mechanical cycle, it follows that they must begin to contract at the moment when a similar shortening process is being induced by the mechanical wave. This would occur if the stimulus to contract were automatically induced by a stretching of the muscle itself. Such a proprioceptive mechanism is well defined among other vertebrate types and its existence in fish would account for many otherwise unrelated facts.

Low Auroras

IT is frequently asserted (*a*) that the aurora occasionally descends to the earth's surface so that it can be seen between the observer and relatively near terrestrial objects, and (*b*) that not infrequently unmistakable sounds accompany auroral displays. Several writers have collected reports from residents in regions where the aurora occurs and a large mass of evidence for the reality of low auroras and sounds accompanying auroral display has been accumulated. In NATURE for March 7, 1931, Prof. S. Chapman reviewed one such collection of reports and expressed his opinion that "These letters make it difficult to deny that auroræ occur, very rarely, quite near the earth, and are sometimes accompanied by noises".

In an article which has just been published in the *Quarterly Journal of the Royal Meteorological Society* (vol. 59, p. 249), Dr. G. C. Simpson discusses the whole problem of low auroras and auroral sounds and comes to the conclusion that "the evidence for low auroras is extremely weak and that when one weighs that evidence against the positive information we have about the nature and position of the aurora one is justified in denying that auroras have ever been observed below a height of 80 km." With regard to sounds, Dr. Simpson says that he is not prepared to deny the possibility that there may be some form of objective sound associated with the aurora, but he very much doubts it.

Dr. Simpson uses three main arguments against the reality of low auroras. In the first argument he points out that we now know that the chief spectroscopic line of the light of the aurora is due to a metastable state of atomic oxygen. This condition of oxygen is only possible when the pressure is very low, and trigonometrical measurements have proved that the height of the ordinary aurora is more than 80 km., where the pressure is sufficiently low. If now an auroral streamer passes from this height to the earth's surface where the pressure is too high for atomic oxygen to exist, a second physical process must come into action, and this process, whatever it may be, would have to come into action in exactly the same proportion as the effect of the first process decreased, for the streamer must remain a streamer, the intensity of the light must not be radically changed and there must be no marked change in its colour. That there should be two such processes is very unlikely on general principles. No suggestion has been made regarding this second process except that it may be due to a high electrical field in the lower atmosphere produced by the aurora itself; but instrumental observations have shown that such high electrical fields do not accompany auroras. Further, no electrostatic field in air at atmospheric pressure can be made in the laboratory to give a glow throughout an extensive region; the highest field attainable only produces localised brush discharges or actual disruptive sparks which are not remotely like the glow of an aurora.

The second argument is based on the principles of perspective. Practically all the observers report that the low auroras look exactly like the normal auroras: they move in the same way, they appear both as streamers and as diffuse glows, they are of the same colour. No difference in breadth of streamer, rapidity of motion, intensity of light or colour is remarked upon. In fact, it is because the low aurora looks like and behaves like the high aurora that their identity is so strongly affirmed. All this is contrary to the laws of perspective. It is generally admitted that the normal aurora occurs in the upper atmosphere at a height of at least 80 km., so that the average distance from the observer must be something like a hundred miles. If such an aurora were suddenly transferred to the neighbourhood of the observer, it certainly would not look exactly the same as it did when it was a hundred miles away. Thus the opinions so strongly held by the observers that they have seen auroras at ground level exactly like the ordinary high auroras is the strongest evidence that could possibly be given against their conclusions.

The third line of attack is to show that all the reported cases of low aurora are optical illusions. The darkness necessary for the aurora to be seen at all makes illusions easy, especially if there is a moon, for moonlight illuminates clouds and snow ridges with an intensity comparable with that of an aurora. Auroras seen between gaps in clouds or between trees when the whole landscape is dark look as though they are in front of the clouds or trees. The aurora appears in the sky simply as light masses and the observer has absolutely no criteria by which to determine the distance; but with ordinary lights their brightness and the sharpness with which they can be seen are the two factors on which judgment of distance is chiefly based. The aurora varies greatly in intensity and without exception the most brilliant auroras consist of rapidly moving, very sharply defined streamers, either in the form of curtains with clear-cut 'folds' or as long narrow shafts with relatively sharp edges. It is therefore not surprising that these auroras appear to be much nearer than those which appear as irregular ill-defined arches and clouds. Many so-called low auroras are simply parts of haloes round the moon or are due to the illumination of fog banks or snow surfaces in bright moonlight.

In concluding his article, Dr. Simpson says that it is not possible to bring the same type of argument against the sound of an aurora as against its low position; but naturally, if the aurora is confined to the high atmosphere, sounds are unlikely. He considers that the observed sounds are psychological, being due to the natural association of sound with the rapid movement of the streamers and the waving of the 'draperies'.

Obituary

MR. CHARLES S. CARTER

THE death of Charles S. Carter, curator of the Museum of the Louth Naturalists', Antiquarian and Literary Society, and president of the Lincolnshire Naturalists Union in 1928 and 1929, at the age of sixty-seven, took place at Louth (Lincs) on April 14. In addition to being curator of the Museum, Mr. Carter was joint honorary secretary of the Society and conchological secretary of the Lincolnshire Naturalists Union, as well as a member of the Lincolnshire Archæological Society.

Mr. Carter belonged to the distinguished band of self-taught amateur scientific investigators, to which local archæology and natural history in Great Britain are so deeply indebted. Not only by their individual labours, but also by the enthusiasm with which they have inspired others, they have kept alive a tradition of local interest and research, in which Great Britain stands almost, if not quite, alone.

Born in 1866 at East Torrington, Mr. Carter was educated for a short time at elementary schools, and then began work in the fields at the age of nine. He was later apprenticed to a cordwainer and worked as a cobbler for the remainder of his life. His interest in archæology and natural history began when he took up his residence in Hampshire, under the influence of Dr. S. Andrews of Basingstoke, with whom he traced the Roman road through Pamber Forest and was a close observer of the excavation of the neighbouring Roman city of Silchester. On removing to Kent, he became associated with the late Benjamin Harrison and Dr. Lewis Abbott between the years 1893–1896 in the collection of eoliths. The period of his greatest activity, however, began when he returned to Louth in 1898. Among other achievements, he discovered the neolithic settlements at Tathwell and Kelstern, recorded several botanical and entomological species for the first time in the county, and found a chalk fossil, *Tylopora lorea*, Lang, which was new to science. Mr. Carter was a frequent contributor to the *Naturalist* and the *Proceedings* of the Lincolnshire Naturalists Union.

DR. JOSEF BAUDIŠ

THE death of Dr. Josef Baudiš, professor of Celtic and comparative philology in the University of Bratislava, on May 4 is announced. Dr. Baudiš was widely known as an authority on the Celtic languages and literatures, more particularly of Erse. In addition to academic studies at the Universities of Prague and Heidelberg, he visited Wales and Ireland annually for purposes of linguistic investigation. His published works include "A Grammar of Early Welsh" (1914), "Structure of the Indo-European Languages", a translation of Czech folk-tales (1917) and a large number of contributions to learned periodicals on early Erse and the Irish saga. He was for a time joint secretary of the Philological Society of London, and one of the founders of *Philologica*.

THE Rev. Frederick L. Odenbach, S.J., for the past forty years meteorologist and seismologist at John Carroll University, Cleveland, Ohio, died on March 15 at the age of seventy-five years. It was through Father Odenbach's influence and initiative that seismographic equipment was installed and stations were organised at fifteen Jesuit colleges and universities in the United States and Canada during the years 1909–12.

We regret to announce the following deaths:—

Mrs. Zelia Nuttall, honorary special assistant at the Peabody Museum of Harvard University and honorary professor of archæology at the National Museum of Mexico, known especially for her work on the ethnology, etc., of Mexico and Central America, on April 12, aged seventy-four years.

Prof. J. G. Porter, professor of astronomy at the University of Cincinnati and director of the Cincinnati Observatory, known for his work on the proper motion of stars, and comet orbits, on April 15, aged eighty-one years.

Mr. A. B. Seymour, since 1886 assistant in the Cryptogamic Herbarium at Harvard University, an authority on parasitic fungi, on March 29, aged seventy-four years.

Col. J. C. B. Statham, C.B.E., C.M.G., author of "Through Angola", a well-known traveller and naturalist in West Africa, on April 29, aged sixty years.

News and Views

King's Birthday Honours

THE King's birthday honours list contains the names of the following scientific workers and others associated with scientific work: *K.T.:* The Earl of Elgin and Kincardine, chairman of the Carnegie United Kingdom Trust. *K.C.B.:* Dr. G. F. Hill, director and principal librarian of the British Museum. *K.C.M.G.:* Sir James Currie, chairman of the governing body of the Imperial College of Tropical Agriculture, Trinidad, and director of the Empire Cotton Growing Corporation. *Knights Bachelor:* Mr. H. T. D. Acland, vice-president of the Dominion Council of the Australian College of Surgeons, Dominion of New Zealand; Mr. A. W. G. Bagshawe, director of the Bureau of Hygiene and Tropical Diseases; Dr. G. C. Clayton, president of the Institute of Chemistry and a director of Imperial Chemical Industries, Ltd.; Dr. R. H. P. Crawfurd, consulting physician, King's College Hospital, registrar of the Royal College of Physicians, London; Dr. Kedar Nath Das, principal of the Carmichael Medical College, Calcutta, Bengal; Dr. W. S. Duke-Elder, ophthalmic surgeon, St. George's Hospital, London; Dr. M. O. Forster, lately director of the Indian Institute of Science, Bangalore; Dr. H. Stuart-Jones, principal of the University College of Wales, Aberystwyth; Col. R. McCarrison, director of Nutritional Research, Indian Research Fund Association, India; Mr. R. S. Pearson, director of the Forest Products Research Laboratory, Department of Scientific and Industrial Research. *C.B.:* Col. W. H. Leonard, late Indian Medical Service; Dr. A. Landsborough Thomson, assistant secretary of the Medical Research Council. *C.M.G.:* Mr. J. L. Gilks, director of medical and sanitary services, Kenya; Mr. J. Strachan, general manager and chief engineer, Federated Malay States Railways. *C.I.E.:* Mr. H. P. Thomas, chief engineer, Hydro-Electric Department, Punjab; Mr. J. de Graaff Hunter, director of the Geodetic Branch of the Survey of India; Lieut.-Col. W. L. Harnett, professor of surgery, Medical College, Calcutta, and surgeon to the College Hospital, Bengal; Mr. J. N. Duggan, professor of ophthalmic medicine and surgery, Grant Medical College, and superintendent, C. J. Ophthalmic Hospital, Bombay. *C.B.E.:* Mr. H. A. Ballou, Commissioner of Agriculture for the West Indies and professor of entomology in the Imperial College of Tropical Agriculture, Trinidad; Mr. E. L. Mitchell, assistant secretary, Ministry of Agriculture and Fisheries; Mr. V. E. Pullin, director of radiological research, Research Department, Royal Arsenal, Woolwich; Maj. C. E. Williams, chief inspecting engineer, Office of the Crown Agents for the Colonies. *O.B.E.:* Mr. A. J. King, executive engineer, personal assistant to the Chief Engineer to the Government of Bengal; Mr. C. M. Pitt, surveyor and engineer, Public Works Department, State of Tasmania. *M.B.E.:* Mr. E. W. Dunn, assistant engineer, Assam; Mr. W. N. Winn, botanist, Royal Botanic Gardens, Kew. *Hon. M.B.E.:* Ragheb Effendi Mohammad, sub-inspector of agriculture, Department of Agriculture and Forests, Palestine. *I.S.O.:* Mr. J. W. Atherton, superintending cartographer and assistant superintendent of charts, hydrographic Department, Admiralty; Mr. J. L. Frood, superintending inspector, Diseases of Animals Division, Ministry of Agriculture and Fisheries; Mr. P. H.

Grimshaw, keeper of the Natural History Department, Royal Scottish Museum; Mr. J. Hedley, staff engineer, General Post Office; Dr. C. F. Lassalle, deputy surgeon-general and medical inspector of Health, Colony of Trinidad and Tobago; Mr. W. McAuslan, engineer surveyor-in-chief, Board of Trade.

France and Great Britain in Africa

M. ALBERT SARRAUT, Ministre des Colonies of France, as chief guest at the African Society's dinner on May 23, was both apt and illuminating in the distinctions which he drew between French and British ideals and methods in the administration of native affairs in Africa. The whole of M. Sarraut's speech was inspired with a deep sense of the responsibility which lies upon the two nations—a responsibility "to protect and improve the destiny of the backward races, weighing more heavily than ever on our shoulders". He pointed out that "we are perhaps on the threshold of new times, in which the load that we bear will grow heavier". Even were there no stronger reason, it was the logical consequence of this view that M. Sarraut should enter on a comparison of the two systems of administration in their attitude towards this great problem. He displayed both knowledge and justice in his comparison. While he claimed for France a nearer approach to the life of the native, he admitted for Great Britain a greater regard for tradition. "You," he said, "listen especially to the prudent, but rather cold counsel of experience. We warm our actions in the flame of apostleship. You, in sum, wish the races to place themselves in a condition to make their own happiness; we wish ourselves to make their happiness urgently and with authority."

IT was evident that M. Sarraut had here in mind, more particularly, the methods of 'indirect rule' of Lord Lugard, of whom, indeed, he spoke most warmly. It is this which gives his speech its greatest significance for those whose interests lie in the application of scientific study to the problems of administration. For he went on to point out, what has indeed been apparent for some time in modifications which circumstances have brought about in French methods of administration, that France and Great Britain, with an identical object in view, are "bending towards a meeting point". With this as his justification he appealed for collaboration—an appeal addressed to all colonising nations. In connexion with M. Sarraud's remarks on Great Britain's regard for tradition and the convergence in method of the two systems of administration, it may not be inappropriate to direct attention to a communication which appears in a recent issue of *Africa* (vol. 6, pt. 2) referring to an expedition of M. Henri Labouret, of the École Coloniale, to French West Africa for the purpose of studying the social and economic organisation and the land system of the natives. Not only did this expedition have the official support of the Ministry of Education and the Minister for the Colonies, but also M. Labouret was accompanied by a graduate of the École with a grant from the Rockefeller Foundation to enable him to become acquainted with conditions in the field. This was in furtherance the policy of M. Labouret, himself, it will be remembered, a former Colonial Minister, of introducing trained ethnographers into the French colonial administrative service.

Scientific Problems of the Pacific

A NOTEWORTHY demonstration of the possibilities of long distance wire and radio telephony was given on June 5, when Lord Rutherford, speaking as the representative of science in Great Britain, delivered an address to the Fifth Pacific Science Congress assembled at Vancouver. Lord Rutherford, in the brief space of some eight minutes, touched on a number of problems closely identified with the work of the Congress. He reminded his audience that the investigation of their region was inaugurated by the British Government and the Royal Society more than a century and a half ago, when they sent Capt. Cook on his first voyage of discovery in the Pacific, accompanied by Sir Joseph Banks and other scientific observers. Lord Rutherford referred to the loss of the famous non-magnetic ship, the *Carnegie*, at Samoa, and to the recent investigations carried out in the Antarctic by the "Discovery" Committee and by the Great Barrier Reef Expedition, off the coast of Queensland. Speaking of notable advances in our knowledge of the transmission of radio waves, which have resulted in the discovery of at least two distinct reflecting layers in the upper atmosphere, he congratulated the Australian Radio Research Board on the valuable contributions its workers have made to our knowledge of this question. He also stressed the importance of the problems of the depopulation of the islands of the Pacific, and of the preservation of the fauna and flora of the region. Lord Rutherford congratulated the Canadian organisers of the Congress on their courage and vision in arranging the meeting in spite of economic conditions, and said: "it is of good augury that representatives of all the countries bordering on the Pacific Ocean have met together in a spirit of friendliness and co-operation to discuss the multifarious scientific problems connected with the Pacific. Science is international, and I trust will ever remain so." After his address, Lord Rutherford had a conversation with Dr. H. M. Tory, president of the Congress, Prof. A. S. Eve, and others.

Legal Size Limits and their Effect upon Fisheries

IN California, more than twenty years ago, when the crab fishery was declining, an investigation carried out by F. W. Weymouth, of Stanford University, showed that the then minimum size limit of six inches was too low, since it permitted the destruction of male crabs before they had a chance to breed. On the evidence put before it, the Legislature decided to raise the limit at which the commercial crab might be taken, to seven inches. The result of so small a change has been remarkable. A few years after the passing of the new regulation, when the first crop of crabs under its protection had reached the seven-inch size, the production of the fishery suddenly doubled, and since then the catch has gone on increasing until now the fishery produces 75,000 dozen crabs more than it did before the law was changed, an increase worth 185,000 dollars to the fishermen (N. B. Scofield in *California Fish and Game*, 1932, p. 260). Yet originally they opposed the change, saying that already at six inches the size limit was too high, and that declining production could be stayed only by permitting the capture of smaller individuals through the reduction of the six-inch limit. Once more, scientifically ascertained facts have triumphed over opinion and so-called experience.

W. E. Dixon Memorials

Two memorials to the life and work of the late Prof. W. E. Dixon, who was reader in pharmacology in the University of Cambridge until his sudden death on August 16, 1931 (see NATURE, 128, 401, Sept. 5, 1931) are being established. The first, already in being, is due to the action of the British Medical Association, which has named one of its most valuable research scholarships the "W. E. Dixon Memorial Scholarship". The second is to take the form of a lectureship. Certain of Dr. Dixon's friends, under the chairmanship of Sir William Willcox, opened in 1931 a fund for this purpose. The final meeting of subscribers to this fund was held at the house of the Royal Society of Medicine on June 1. This meeting resolved that the money collected (£700) should be used to establish a "W. E. Dixon Memorial Lecture" which should be delivered biennially or triennially, on some subject of pharmacological or therapeutic interest. The Royal Society of Medicine was invited to undertake the trusteeship of the fund. The response to the appeal which was issued has been extraordinarily wide. Present and past students, colleagues, former colleagues, and personal friends in Great Britain, the United States, and on the Continent, have all contributed. In addition, donations have been sent from representatives of commercial firms, and from several learned societies, both at home and abroad. This response shows how wide was Dixon's influence, and how warmly his qualities were appreciated.

Composition of the Stars

ON June 1 the annual Halley lecture at the University of Oxford was delivered by Prof. Henry Norris Russell, professor of astronomy and director of the University Observatory, Princeton, on the subject of the "Composition of the Stars". He remarked that the statement of Comte about a century ago, that no human being could ever learn anything of the composition of the stars, was speedily invalidated by the detection of various elements in the sun by the employment of spectrum analysis. From the adaptation by Huggins of suitable spectroscopes, it was soon ascertained that the same substances as occurred in the sun were also to be found in the stars. It was next made clear that the stars fell into natural classes, white, yellow and red, with intergrades. The stellar conditions of extreme heat made it possible to investigate the properties of matter at their simplest. The intensities of the lines of the spectrum were almost as important as their position. Iron was shown to be abundant in the sun, copper next, silver comparatively rare. Fifty-eight elements are now known in the sun; improvements in apparatus will no doubt disclose others. Sir Norman Lockyer was right in surmising that atoms themselves are structural, they disintegrate in white stars; he was again right in holding that the width of a line is proportional to the number of atoms producing it. In the interior of stars, the atoms of light elements are disintegrated by the collision of protons with the nuclei. There is an unsearchable part of the solar spectrum; the lines of the missing elements may occur within it. At the conclusion of the lecture, diagrams were shown which gave the number of atoms actually concerned in different kinds of stars.

Artificial Transmutation of the Elements

ON June 2 at Oxford, under the auspices of the Junior Scientific Club, the annual Boyle lecture was delivered by Lord Rutherford, who took as his subject the "Artificial Transmutation of the Elements". He described the pioneer achievement of Messrs. Cockcroft and Walton at the Cavendish Laboratory in applying the high-voltage method of generating fast streams of protons for producing atomic transformation, and detailed recent developments of method by which it was possible to obtain still greater results at a lower voltage. Further modifications had led to conclusions of high interest, and the new type of projectile now in use will no doubt result in extending the knowledge of types of possible transformation. It was probable that further assaults would be made on the stability of the nucleus, and there was already evidence of the appearance of a positively charged particle of mass comparable with that of the negative electron.

Constitution and Temperament in Man

IN *Scientia*, 53, 4, K. H. R. Edwards outlines the chief lines of approach to the study of the relationship between constitution and temperament, namely, the genetic, the teleological, the physiological, and the psychopathological. He realises that such differentiations are of descriptive rather than practical utility. He discusses the data relevant to the problem as presented by Bartlett, McDougall, Kretschmer, Pavlov, and Jaensch, and, perhaps somewhat optimistically, concludes that in the near future the advances in physiology, psychiatry and psychology will solve the problem. Discussions on temperament are complicated by the vagueness of writers as to the meaning of the word, coupled with the fact that popularly it is used for emotional instability, so that a well-balanced person would not be accredited with any temperament. The concept arose out of the observation that individuals differ in susceptibility to disease, and the hypothesis that this was due to some difference in physiological make-up (crasis, temperamentum, complexion) is at least as old as Hippocrates, although generally known in the form given to it by Galen. It is therefore a legitimate problem to investigate the truth of this hypothesis, and a survey of the literature shows that this has motivated many 'arm-chair' theories and a little experimental work. Physicians also observed that variation in disease susceptibility seemed to be linked with structural differences and psychological differences, and this presents another problem. The observed psychological differences are for the most part emotional in character. We thus have three variables, each very complicated, and for each we need measures. With the passing of time, emphasis has been placed on the psychological differences, but very often one of the old hypotheses is implicit.

Royal Cornwall Polytechnic Society

INCLUDED in the ninety-ninth annual report of the Royal Cornwall Polytechnic Society is an account of the annual meeting held at Falmouth in February 1932. On that occasion the president remarked that he looked back with pride on the very good work that the Society had done since its institution. "It has for 99 years been fostering useful crafts, promoting utilitarian arts, and promulgating the logic and tenets of science, all in the interests of the Cornish industries." The principal event during the preceding year had been the renovation and adaptation of the premises of the Society for receiving the Falmouth Museum, the control of which had been transferred to the Society from the Town Council. The renovations had cost about £1,450. Together with the usual information about membership and finance, the report contains accounts of the summer meeting and seven original contributions. Among these is a short but useful account of the development of explosives and a sketch of the life and work of the Cornish engineer Michael Loam (1797–1871) the inventor of the man engine. Before the days of steam winding engines, miners generally ascended and descended the shafts by ladders, a practice which proved very injurious to their health. At the first meeting of the Society premiums were offered for some improvement on the existing methods and in 1838 a sum of £500 was offered for the application of machinery to facilitate the ascent and descent. Through these offers Loam was led to the invention of the man engine consisting of rods fitted with platforms, which were raised and lowered several feet at a time by an engine. There were fixed platforms in the shaft and men ascended or descended by stepping alternately on to a fixed platform and then a moving platform. The same plan was in use in Germany.

The Pepys Tercentenary

IN commemoration of the tercentenary of the birth of Samuel Pepys, which fell on February 23, a lecture was delivered by Mr. Edwin Chappell, at Clothworkers' Hall, Mincing Lane, London, on that date, recalling the primary circumstances of Pepys's career, these being brought into pleasant and effective remembrance by means of a series of one hundred and forty lantern slides. The lecture was published in the *Mariner's Mirror*, vol. 19, No. 2, April 1933. Pepys was Master of the Clothworkers' Company in 1677, and thirty-six years ago a lecture on Pepys was given in its Hall by Mr. H. B. Wheatley. Since then much valuable Pepysian literature has been issued, and Mr. Chappell himself has made a close study of the subject. We learn that the name Pepys may be pronounced, without criticism, as if written 'Peppis'. The full story of Pepys's association with the pioneer leaders in philosophical inquiries of his period remains to be written ; but it would not be advisable to attach special personal significance to Pepys's imprimatur on the title page of Newton's "Principia" ; it was the outcome of a formal request made to Pepys to license the book, and no more. Some attention was given in the lecture to contemporary portraits of Pepys. Kneller's canvas, which hangs in the rooms of the Royal Society, was Pepys's own gift, made whilst president, and it has never left the Society's keeping. If, as Mr. Chappell remarks, "it seems to be accepted that this portrait is a copy", then Pepys's sense of prestige, and the understanding of his colleagues (one of them Evelyn), are called in question.

Dangers of Very High Voltages

THE Institute of Fire Engineers has recently carried out experiments at Croydon on an overhead wire carrying current at 132,000 volts. A jet of water was projected against this wire at a distance of about thirty feet by means of a fire hose, and pressures of about fifty volts were measured between the nozzle and earth. The fireman said that only a prickly sensation was felt in his hands. An account of the experiments is given in the *Electrical Times* of May 25. In an editorial comment it is pointed out that it is not to be concluded from these experiments that playing a hose on high tension wires is safe. Nothing serious should happen to the man who operates the hose at earth potential, but if a jet of falling water in contact with the wire touched a bystander whose shoes happened to be wet, it might easily kill him. A recent law case in the Leeds County Court illustrates the dangers that arise when any conductor, even a bad conductor, touches a grid main. The mast of a barge being towed on the canal between Goole and Barnsley in Yorkshire touched the grid overhead line. The bargee, who was on the towpath at the time, heard a scream. Running back, he saw all the barge ablaze and his son lying on his back "as if he were dead". All the iron of the mast and the deck was burned and twisted. The chains became liquid and poured about like water and the mast fell down. His son had to go to hospital and the barge was laid up after the accident for six months. As the high tension wire had been strung across the canal at the prescribed height, the bargee got no damages as it was a case of "contributory negligence".

Electrification of an Ice Factory

THE Grimsby Ice Company has now the largest ice factory in the world. The trawlers of Grimsby fish in the North Sea and off the west coast of Greenland. All the six hundred trawlers take supplies of ice when they set off for the fishing grounds, each boat taking about 15 tons when going to fish in the North Sea and four times as much when fishing in Icelandic waters. In the *Metropolitan-Vickers Gazette* for March and April, J. H. Lamb gives an interesting account of the electrification of the factory. The plant is capable of turning out 1,200 tons of crushed ice a day and delivering it into the holds of the fishing vessels by means of a fleet of motor lorries. Before reconstruction, the plant was driven by ponderous slow-speed engines. It has now been replaced by electrically driven compressors and all the auxiliary equipment has been completely electrified. The refrigerating medium is ammonia and the ammonia gas is raised in the compressors to a pressure of between 100 lb. and 180 lb. per sq. in. It is next cooled and liquified by passing through a condenser. The liquid then passes to the refrigerating plant in tubes surrounded by brine. The liquid expanding to its gaseous form absorbs heat from the brine which is cooled below 0° C. The cold brine is circulated in a large tank containing the cans which hold the pure water to be frozen. The four compressors are driven by four motors each of 600 horse power. These are supplied with electric power by the Grimsby Corporation, through a transmission line at 6,300 volts. The Ice Company is developing a new process of freezing which it is hoped will popularise frozen fish. Complaints have been made that frozen fish are 'soft' or 'mushy' when thawed. By rapidly freezing them the water between the flakes of the fish does not crystallise and when thawed it is stated that the fish is just as firm and white as fresh fish.

Progress at the Indian Institute of Science, Bangalore

THE April number of *Electrotechnics*, the journal of the Electrical Engineering Society of the Indian Institute of Science at Bangalore, proves that rapid progress is being made in developing its activities. It has been decided to instal in the Electrical Department a radio frequency standard which will enable measurements to be carried out with the highest accuracy over a range extending from 10 to 24,000 kilocycles per second. The Government of India will recognise the Institute's certificates. It is hoped that this will prove the first step towards the establishment of a National Physical Laboratory of India. An obituary notice of the late Dr. Alfred Hay, who was appointed to the chair of electrical technology at the Institute in 1908, appears in this issue. Many of his students have done good work in electrical research. He was sadly missed by them when he left for England in 1923. He died in Cyprus in 1932. He was succeeded by Prof. J. K. Catterson-Smith, who is now Siemens professor of electrical technology at King's College, London. He did excellent work in developing radio research at Bangalore. Sir C. V. Raman became director of the Institute in succession to Dr. M. O. Forster, whose well-merited knighthood announced among the King's birthday honours will give particular pleasure to his friends. An interesting account is given of the Uhl River hydro-electric scheme. The combined output of the power stations will be 150,000 kilowatts. From an article by C. B. Sethna, director of the Bombay broadcasting service, on the progress of broadcasting in India, it appears that Calcutta, Bombay and Madras have now a regular broadcasting service. What is wanted seems to be a few high-power broadcasting stations at the centres of culture of the important linguistic areas of India.

Exchange of Goods during Economic Depression

REVERSIONS to simpler types of economic organisation are not uncommon in times of economic stress, and an interesting example is provided by the development of the exchange of goods and services by barter in the United States during the present economic depression. In 1931 a small exchange was opened in Salt Lake City to facilitate the barter of unemployed labour for surplus farm produce. Since then, the movement has spread rapidly to many parts of the country and now covers a wide range of trades and professions. A National Development Association was formed to organise the exchanges, and in July 1932 this body introduced a medium of exchange in the form of paper tokens known as 'scrip'. This 'scrip' represents to the holder the value of the produce or services he has provided and can be exchanged for an equal value of other produce, being readily accepted by traders, shops and theatres. The issue of 'scrip' is, however, far from being an innovation in the United States, and recently Mr. T. T. Belote, curator of history in the Smithsonian Institution, arranged an interesting exhibition of earlier examples. During the decade 1832–42, numerous bank failures led to much money being withdrawn from circulation, and to meet the monetary stringency a large number of so-called 'hard-time tokens' were issued. Some of these bore laudatory or satirical legends referring to the financial policies of Jackson or Van Buren. In the same period, many commercial firms issued a kind of token money known as 'store cards'. Up to the Civil War, paper scrip issued by banks and private firms of almost every imaginable character circulated extensively. Some of it was well-drawn and finely engraved, but so rapidly did many of the issues deteriorate in value that they came to be known as 'skin plasters'.

B.D.H. Products

WE have received from the British Drug Houses Ltd., London, N.1, leaflets describing the nature and uses of certain of their products. 'Spironine', a stable elixir, contains in each fluid drachm 3 grains of di-iodo-caffeine hydroiodide together with the soluble constituents of 7½ grains of coffee. It is recommended for the relief of asthma during the intermittent paroxysms. It should be given at the onset of an attack, its effect being immediate. By checking the paroxysms it prevents the development of such chronic conditions as emphysema and bronchitis. Another drug of great value in the treatment of asthma is 'Ephedrine', which also finds a place in the treatment of hay fever and whooping cough. Ephedrine B.D.H. is issued in tablets and in solution in ampoules, and as an elixir, an inhalant, a throat-spray and a nasal jelly. 'Acriflavine B.D.' is a useful antiseptic for the treatment of wounds and local septic conditions. It can also be administered by mouth (as neutral acriflavine or euflavine in enteric coated tablets) or by intravenous injection. A new edition of the firm's vitamin booklet has also been prepared. It describes the uses in general practice of 'Radiostoleum' (vitamins A and D concentrate), 'Radio-Malt' (containing vitamins A, B_1, B_2, and D), 'Radiostol' (vitamin D) and 'Avoleum' (vitamin A). 'Radiostoleum' liquid is standardised to a 'blue' value of 500 by the Carr-Price test and contains 3,000 international units of vitamin D (calciferol) per gram. The capsules have a 'blue' value of 1,000 and each contains 1,200 vitamin D units. It is recommended as a preventive against infection and also in the prophylactic and curative treatment of rickets and osteomalacia and dental caries. 'Radiostol' solution is prepared from pure crystalline calciferol. It is standardised to contain 3,000 vitamin D units per gram (B.P., 1932). 'Avoleum' is standardised to a 'blue' value of 1,000.

Pathology and Bacteriology at Leeds

THE annual report for 1932 of the Department of Pathology and Bacteriology, University of Leeds, by Profs. M. J. Stewart and J. W. McLeod, recently issued, surveys the teaching and research work carried out in the laboratories. The research work includes investigations on industrial pulmonary diseases, studies in renal function, and on different cultural types of the diphtheria bacillus. In four hæmatite miners an extreme degree of pulmonary fibrosis was detected. In cancer research, Dr. Bonser has obtained results strongly suggesting that it is possible to breed a race of mice which respond very early to tumour induction by means of tar.

The Ross Institute and Hospital for Tropical Diseases

THE annual report and accounts for 1932 of the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W.15, records an increase in receipts of £1,051 compared with 1931, and the net loss on the year's working is reduced to £429. Additional donations and annual subscriptions would be very welcome so that the work of the Institute may be extended, and income and expenditure may at least balance. Information is given respecting the activities of the Institute in various parts of the world, particularly in regard to anti-mosquito measures and malaria control, together with a summary of the research work conducted in the laboratories and elsewhere.

Announcements

THE Research Defence Society will hold its annual general meeting at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1, on June 22 at 3 p.m., when the seventh Stephen Paget memorial lecture will be delivered by Major-Gen. Sir Leonard Rogers on "The Saving in Life and Suffering, due to Medical and Veterinary Research, with special Reference to the Tropics".

WE have received from Messrs. W. Watson and Sons the thirty-third edition of their catalogue of microscopic objects. The contents of this list, which are well classified, include a wide range of slides useful for teaching and demonstration purposes, and many that will appeal to the microscopist who desires slides of named species, for example, of diatoms, prepared for careful examination.

ANOTHER volume of collected researches, published from the wards and laboratories of the London Hospital during 1932, has been issued by the Publications Committee (London: H. K. Lewis and Co., Ltd., 136 Gower Street, W.C.1. 7*s*. 6*d*. net). The papers included, all of which have been published elsewhere, deal with many branches of the science and art of medicine and form a notable contribution to the subject.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in mathematics at the University College of South Wales and Monmouthshire, Cardiff —The Registrar (June 12). A temporary assistant at the Mersey Laboratory of the Department of Scientific and Industrial Research—The Secretary, 16, Old Queen Street, Westminster, S.W.1 (June 13). Two full-time lecturers in chemistry at the Polytechnic, Regent Street, London, W.1—The Director of Education (June 16). A lecturer in physiological chemistry at Guy's Hospital Medical School—The Dean, Guy's Hospital Medical School, London Bridge, S.E.1 (June 19). A junior scientific officer at the Fuel Research Station, East Greenwich—The Secretary, Department of Scientific and Industrial Research, 16, Old Queen Street, Westminster, London, S.W.1 (June 19). A full time medical radiologist in the Western Infirmary and University lecturer in the University of Glasgow—J. Matheson Johnston, 87, Union Street, Glasgow (June 21). A professor of electrical engineering at University College, Nottingham—The Registrar (June 21). A principal of the Pontardawe Mining and Technical Institute and Junior Technical Day School—The Director of Education, County Hall, Cardiff (June 22). A lecturer in mathematics and an assistant lecturer in electrical engineering at the Manchester Municipal College of Technology—The Principal (July 1). A professor of mathematics at the Auckland University College, New Zealand—The Secretary of the Universities Bureau of the British Empire, 88a, Gower Street, London, W.C.1 (Aug. 1). A mycologist in the Department of Plant Pathology at Rothamsted Experimental Station, Harpenden—The Secretary (Sept. 15). A professor of organic chemistry at the University of Liverpool—The Registrar. An assistant civil engineer and an assistant mechanical engineer for the Commissioners for the Port of Rangoon—Sir Alexander Gibb and Partners, Queen Anne's Lodge, Westminster, S.W.1.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Development of Fuseaux, Aleuriospores, and Spirals on detached Hairs infected by Ringworm Fungi*

So long as hairs infected with *Microsporon audouini*, *Trichophyton gypseum*, and other ringworm fungi remain attached to the body, the fungi attacking them consist only of hyphæ and small round spores. These spores arise by the rounding-off and disarticulation of the cells of the hyphæ and may be regarded as *chlamydospores*. In contrast to the lack of variety of organs found in a hair stands the number of characteristic structures which are produced when these fungi are grown on synthetic and natural media (Sabouraud[1], Langeron and Milochevitch[2]). Thus *Trichophyton gypseum*, when grown on Sabouraud's maltose-peptone agar, develops: (1) *conidia*, resembling somewhat those of the form-genus *Sporotrichum*, which are termed by medical mycologists *aleuriospores*; (2) large, pleuriseptate, spindle-shaped *macroconidia* which are termed by medical mycologists *fuseaux*; and (3) helically coiled hyphæ, known as *spirals*.

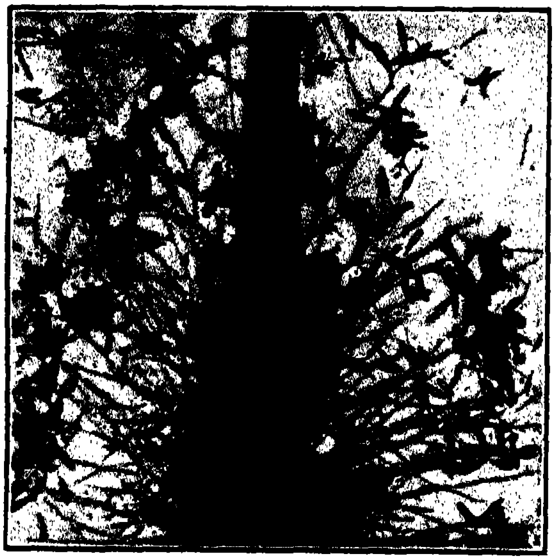

FIG. 1.

FIG. 1.—Human hair naturally infected with *Trichophyton gypseum*, showing development of fuseaux after 16 days in a moist cell without the addition of any nutrient medium. Photographed in air. × 273.

It must be assumed that these organs, hitherto known only in culture, develop only under artificial conditions or else, as Sabouraud[3] has suggested, they form part of a saprophytic stage in the life-history of ringworm fungi which so far has remained undiscovered in Nature.

One characteristic of ringworm is that the hairs on the lesion, when invaded by the fungus, become brittle and tend to break off. It can easily be imagined that hairs from ringworm lesions on animals must often fall to the ground in moist places. An attempt has therefore been made to reproduce experimentally the moist conditions in which such infected hairs may find themselves on reaching the ground.

In August, 1932, a boy suffering from kerion of the scalp—a deep, suppurating form of ringworm—was admitted to the Winnipeg Children's Hospital. His parents believed that he had acquired the disease from infected cattle on their farm. Hairs were removed from the lesion and, when examined with the microscope, were found to be infected with a *Trichophyton* belonging to the ectothrix microides group of Sabouraud. Isolations made from other hairs gave cultures of *Trichophyton gypseum*. Some of the infected hairs were stored in a dry place between sterilised glass slides. A few of the hairs which had remained dry for about six months were caused to hang from the under sides of the cover-glasses of van Tieghem cells, but they were not covered with water or a drop of culture medium. These hairs were then exposed to various conditions of humidity controlled by solutions of known osmotic pressure placed in the bottom of the cells. Thus the hairs and the fungus within them were supplied merely with water vapour.

Germination of the chlamydospores in the hairs suspended in the van Tieghem cells soon took place, and each hair slowly became surrounded by a fringe of mycelium. The ends of many of the hyphæ then thickened and formed macroconidia (fuseaux). These macroconidia increased in size and abundance until they formed a halo around the hair, as shown in the photomicrograph reproduced in Fig. 1.

Not only were macroconidia formed by the mycelium which had grown out of the hairs but conidia (aleuriospores) and spirals also. The conidia were much less conspicuous than the macroconidia, from which they could be readily distinguished by their smaller size and rounded unicellular structure. The spirals were closely coiled and resembled the spirals usually produced in cultures on agar and other media.

Macroconidia (fuseaux) and conidia (aleuriospores) have also been obtained on detached hairs naturally infected by *Microsporon audouini* and by *M. felineum*. Other species of dermatophytes are now being studied with the help of the new technique.

The experiments just described demonstrate that a ringworm fungus present in naturally infected hairs may, when the hairs are placed under suitable conditions of humidity without the addition of any nutrient medium, enter upon a new phase of growth. In this saprophytic stage of the life-history, spore-forms and other organs are produced which hitherto have been found only in artificial cultures.

Although ringworm fungi will grow upon various sterilised natural media, such as horse-dung, straw, and grains of cereals, it has not yet been shown that they can flourish on these substrata under natural conditions which involve competition with other organisms. In the fallen infected hairs, on the other hand, a dermatophyte is in an advantageous position relatively to other organisms. By the time the infected hairs and scales fall from the body, the parasite has thoroughly penetrated their substance and converted much of it into fungal spores. A considerable amount of fungal protoplasm is therefore lying dormant within the hair ready to begin growth at once when brought into a suitable environment. Further, a fungus growing on such keratinised tissues as hair and scales has the advantage of freedom from competition, since it is growing on a substance which few other organisms are able to attack. It is possible that saprophytic stages of ringworm fungi may one day be found in Nature on various substrata other than fallen hairs. However, it may well be that cast-off hairs and epidermal scales are the most important natural substrata on which ringworm fungi pass their saprophytic existence and produce spores capable of infecting new human and animal hosts.

The authors desire to express their thanks to Prof. A. H. Reginald Buller for assistance in the preparation of the manuscript.

A Fly Pest of Timothy Grass

ATTENTION has been directed in recent years to the occurrence of a partial 'stripping' of the flowerheads of Timothy Grass (*Phleum pratense*) before these have emerged from the sheath. In Norway, 1914[1], Sweden, 1912–1916[2], Austria, 1921–1923[3], and Russia, 1928–1929[4], this damage has been traced to the maggots of Cordylurid Diptera, especially *Amaurosoma armillatum* Zett. Similar attacks have been noticed in Scotland and in 1931 Macdougall[5] suggested that "a species of Amaurosoma" might be the cause.

In June and July 1931 we received, from the neighbourhood of Stirling, specimens of the grass showing the damage in progress. The larvæ, which were then feeding, afterwards pupated in soil and were kept in the laboratory until flies emerged in April and May of 1932. These were submitted to the Imperial Institute of Entomology and were identified by Sir Guy Marshall as *Amaurosoma armillatum* Zett. With them were sent flies caught by us, in the original locality, on June 8, 1932, which proved to be of the same species. Some of the latter mated and laid eggs, on Timothy grass, in the laboratory.

The egg is approximately 1 mm. in length, pale yellow in colour, tapering towards both ends, convex and smooth below, having four longitudinal ridges above and a reticulate pattern between these. Similar eggs on Timothy grass were brought in from the field on June 1, 1932. In all cases the egg was laid at the base of a leaf-blade, just above the ligule, long axis parallel to the veins of the leaf, and on a plant of which the flower-head had not yet appeared. We have never found more than one egg on a leaf, seldom more than one on the same plant.

The eggs laid in the laboratory hatched in four to five days and the larvæ gained access to the head, in most cases between the edges of the folded leaves, in one case by perforation of the leaves. Usually not more than one larva has been found in one head. The larva was seen to work round the head and downwards, devouring the flower-buds and cutting off the glumes. As much as one third of the head might be stripped.

When full-fed the insect drops to the ground and pupates immediately beneath the surface of the soil among the roots. It remains in the puparium throughout the following winter. We have found no evidence of a second generation in the year.

Further investigations are being made, in the laboratory and in the field.

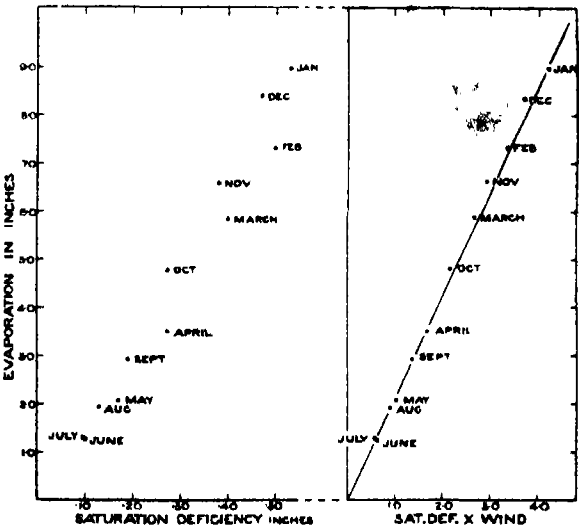
Effect of Rainfall-Evaporation Ratio on Insects Inhabiting the Soil Surface

CERTAIN insects inhabiting the soil surface are markedly affected by soil moisture, largely owing to its influence on the humidity of their surroundings. Soil moisture is primarily dependent on the ratio of rainfall to evaporation (R/E); important secondary factors being soil type and its vegetative covering. If values for the R/E ratio in an area are known, a useful index to the conditions in the micro-environment at the soil surface is available for ecological studies[1]. Evaporation from a free water surface is nearly proportional to the saturation deficit of the air, other variables being constant. Saturation deficit is available for stations where temperature and relative humidity are recorded, and evaporation values can be determined approximately by reference to evaporation records for comparable stations. Owing to the variables involved, particularly wind and the character of the soil surface, the computed values can be only roughly approximate.

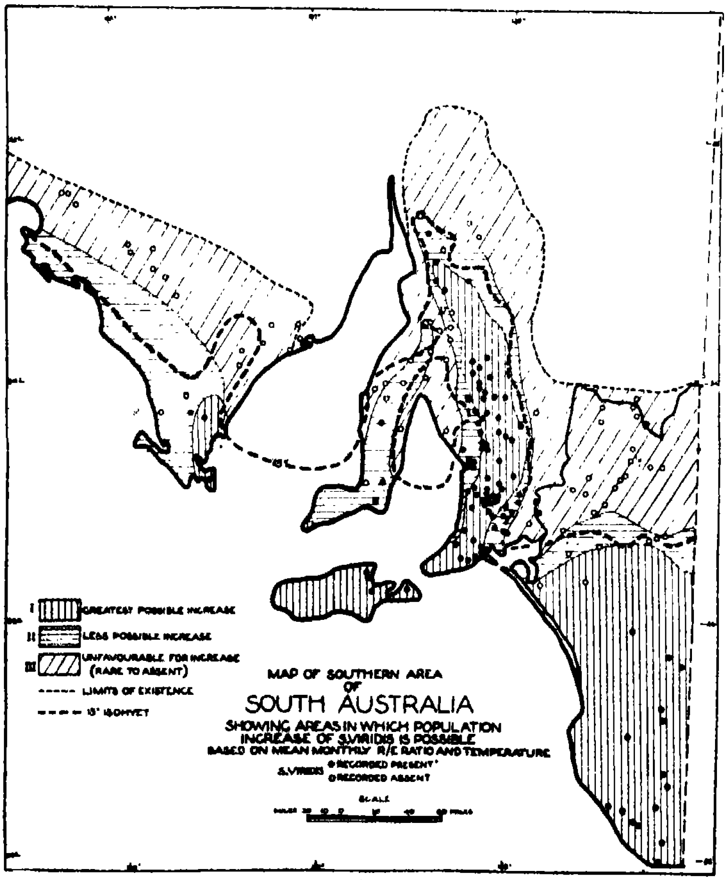


(*a*) (*b*)

FIG. 1.

I have used a method with reference to *Sminthurus viridis* L. (Collembola), in South Australia, to show the months in which the species will occur and its probable geographical distribution over the State.

In Fig. 1(*a*) the mean evaporation each month at Adelaide is plotted against saturation deficit. Values for the latter were calculated from the mean relative humidity (9 a.m.) and mean air temperature. In Fig. 1(*b*) the saturation deficiency value was multiplied by the mean total wind miles for the month (abscissa)[2]. The significance of the wind factor is clearly shown.



I GREATEST POSSIBLE INCREASE
II LESS POSSIBLE INCREASE
III UNFAVOURABLE FOR INCREASE (RARE TO ABSENT)
LIMITS OF EXISTENCE
15" ISOHYET
MAP OF SOUTHERN AREA OF SOUTH AUSTRALIA
SHOWING AREAS IN WHICH POPULATION INCREASE OF S.VIRIDIS IS POSSIBLE
BASED ON MEAN MONTHLY R/E RATIO AND TEMPERATURE
S.VIRIDIS ● RECORDED PRESENT ○ RECORDED ABSENT
SCALE

FIG. 2.

The mean monthly saturation deficit was obtained for 21 stations in the State, from temperature and humidity records, and monthly evaporation values were calculated by reference to evaporation data for Adelaide. In making the computations, values for wind were considered to be the same as for Adelaide. Mean monthly rainfalls from 220 stations (including the 21 stations above) were used and maps were prepared showing the areas and months in which rainfall exceeds evaporation. The ratio $R/E = 1$ was taken as the critical value below which the conditions may become too dry for the active stage of *Sminthurus*. From these maps, together with monthly isotherms, the areas in the State climatically suitable for population increase of *S. viridis* were defined (Fig. 2). The values for R/E and for temperature in relation to development were used to indicate the months in which the greatest increase may occur. The predicted areas agree closely with the actual records. In areas II and III, soil type and absence of suitable food plants are important edaphic factors restricting the spread of the species in certain districts. The presence of the insect on the swamps along the River Murray in areas II and III is due to soil type and artificial irrigation. The work will be described in full in the *Australian Journal of Experimental Biology and Medical Science*.

Insect Transmission of Virus *A* of Potatoes

IT has been proved in previous work carried out in this laboratory that the crinkle disease of potatoes is a virus complex caused by the combination of the virus of simple mosaic and a hitherto undescribed constituent which has been designated virus *A* by Murphy and McKay[1]. It had already been shown by Salaman[2] that crinkle was not transmitted as such by needle inoculation, and it is now well established that the disease obtained in this way is equivalent to a simple mosaic or to the needle-borne but not aphis-borne disease (due to virus *X*) secured by K. M. Smith[3] from Up-to-Date. In other words, virus *A* is dropped on needle inoculation.

When attempts were made to transmit crinkle by means of the aphis *Myzus persicæ*, Sulz. it was found that the full crinkle complex was not produced, but that there resulted in healthy President potato a form of veinal mosaic of a mild nature. Crinkle originating from both President and Irish Chieftain gave the same result. Examination of this disease showed that it was not simple mosaic, for it produced acronecrosis by grafting on British Queen and Up-to-Date and vein-banding by needling to tobacco. Attempts to infect *Datura Stramonium* by needle, graft and aphis produced no visible symptoms. These manifestations are the characteristics of virus *A*. When simple mosaic was grafted on President containing the aphis-transmitted disease, typical and persistent crinkle symptoms developed in the stock plants.

Virus *A* was also transmitted direct from Irish Chieftain potato carrying this virus by means of *Myzus persicæ* to healthy President, British Queen, Up-to-Date, tobacco, and President containing a simple mosaic derived by needle inoculation from crinkle. The results were the same as before: a mild veinal mottle resulted in healthy President, acronecrosis in British Queen and Up-to-Date, vein-banding in tobacco, and crinkle in President containing simple mosaic.

It is, therefore, clear that *Myzus persicæ* is an efficient vector of virus *A* from potato to potato and tobacco, and so far as crinkle is concerned it transmits it selectively to the exclusion of the simple mosaic element. This is very convenient in experimental work, since virus *A* is otherwise inoculable with difficulty. On the other hand, if another virus were present of which *Myzus persicæ* was also a vector, it is likely that the insect would transmit both. The aphis-borne virus (afterwards identified as *Y*) transmitted by *Myzus persicæ* from the crinkle in Myatt's Ashleaf used by K. M. Smith[4] was not identical with virus *A*, as is seen, among other reasons, from the fact that Smith's *Y* was readily returned by needle from tobacco to potato, in which it produced 'crinkle and leaf-drop streak' in the variety President. Virus *A* is not so returnable, nor does it ever in my experience produce such symptoms in this variety. As Murphy[5] has already suggested, it is possible that virus *A* was also present in Smith's crinkle, in which case it would be carried by the insect along with *Y*, and since both produce similar vein-banding symptoms in tobacco, no evidence of its presence in that plant would be available, while the effect of this particular *Y* on President was so severe that the faint symptoms of *A* would not become visible.

There is some evidence to show that *Myzus circumflexus*, Buckt. may also act as a vector of virus *A*. *Macrosiphum solani*, Kalt. (*Myzus pseudosolani*, Theob.) failed to transmit the virus, as did the capsids *Lygus pabulinus*, Linn. and *Calocoris bipunctatus*, Fabr.

Insects and Micro-Climates

MESSRS. LEESON and Mellanby have directed the attention of entomologists to the changes in temperature in small local areas due to evaporation[1]. The present communication is offered in elaboration of their suggestion.

In Morelos, Mexico, there is a long dry season—September to May—followed by a period of steady rains from June through July, August and part of September. In July, during the rains, the relative humidity may stay so high as 90 per cent for days ; while in March, the height of the dry season, it may go so low as 15 per cent. This very low humidity, however, is in all probability never experienced by the Mexican fruit fly, *Anastrepha ludens* (Loew) ; nor for that matter, the high temperature of the day. Direct observations of the flies during the hot arid days showed that they favour the under side of the leaves of the mango trees. The thickness of the foliage of these trees and their high rate of transpiration account for a difference of ten degrees and more (Fahrenheit) from the periphery to the centre of the tree. Transpiration takes place almost entirely on the lower side of the leaves ; and there the flies are to be found during the dry season.

The mango is the chief host of the Mexican fruit fly in Morelos. Up to the present, the attention of observers generally has been focused exclusively on the suitability of the mango fruit for the egg and larval stages of the fly. In this, I think, we have been in error. The compactness of the foliage and the amount of transpiration render the tree itself highly suitable as an environment for the adult flies in respect to temperature. The latter move about surprisingly little in the course of their lifetime, indulging only in short circular flights in ordinary circumstances ; and as mango fruits are entirely acceptable as an egg-laying medium, a high degree of infestation—about 99 per cent—is the result.

The same kind of effect can be observed in the case of *Opius crawfordi* (Vier), the chief parasite of *Anastrepha ludens*. A study of *Opius* adults was made under laboratory conditions, and showed that the difference between 20 and 45 per cent relative humidity is physiologically enormous, when judged by mortality figures. Under field conditions, *Anastrepha* larvæ in sweet limes are parasitised by *Opius* to a very much lesser extent than larvæ in mangos, even though both types of tree grow in close proximity in the same grove. It was found that the humidity among the open-branched sweet lime trees is very much lower than among the densely foliaged mangos.

The concept of an association between insect and host fruit should be broadened to include the tree itself. The rate of transpiration of a host plant may be a determining factor in the survival of an insect, for two reasons : the lowering of the air temperature by evaporation from leaf surfaces, and the local increase in atmospheric humidity from the same source.

Efficiency of Anti-Stokes Fluorescence in Dyes

ACCORDING to Kautsky and his collaborators[1], the majority of the molecules of dyes investigated by them, among which were also the molecules of fluoresceine, show an ability to phosphoresce when 'energetically isolated', for example, when adsorbed by convenient adsorbents. We can assume therefore that in such molecules there must be at least one metastable energy level *M* (Fig. 1), situated lower than the level *F* reached immediately after absorption. From the state *F* the molecules can pass either to a normal state *N*, emitting the band *F–N* (fluorescence), or to the metastable state *M*. The probability of the transition *M–N* is very small. Therefore when the temperature is sufficiently high, a great majority of molecules will be raised thermally from the level *M* to *F* and will be able to emit the band *F–N* (phosphorescence at room temperature). At low temperatures, direct transitions *M–N* take place. These transitions are accompanied by the emission of a phosphorescence band which is displaced towards the red relatively to band *F–N* ; the duration of phosphorescence increases greatly (phosphorescence at low temperatures).

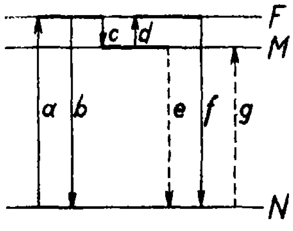

FIG. 1.—Energy levels in a phosphorescent molecule. *a*–absorption, *b*–fluorescence, *c*–transition to metastable level, *d*–thermal excitation, *e* and *f*–phosphorescence, *g*–absorption of very small transition probability.

As the mean life τ of the state M is much longer than that of the level F, the phosphorescence is quenched appreciably more than fluorescence. This follows from the formula[2] $I = \frac{I_0}{1 + k\tau}$, where k is the probability of a quenching act, I the observed intensity of photoluminescence.

The absorption band N–M (inverse transition) must also appear if the transition M–N take place, notwithstanding its small probability. However, it will have a very small intensity as compared with band N–F.

Under the influence of disturbing fields, for example of the surrounding molecules of the solvent, the probability of transition N–M can become appreciably greater than that of the isolated molecule. In solutions, practically all the molecules which have reached the level M in any possible way will be quenched. Therefore the absorption band N–M must be completely inactive.

Such inactive bands, overlapping on the longer wave-length side the active absorption bands (N–F), can cause the falling off of efficiency as observed in fluoresceine solutions[3,4,5]. It is to be noted in this connexion, that in the region of abrupt falling off of yield, the values of absorption coefficients of fluoresceine solutions reach only from 0·2 to 2 per cent of the maximal value.

In the above considerations I have supposed for the sake of simplicity that the levels for absorption and emission acts are identical. I have dealt elsewhere with the relative displacements of emission and absorption bands.[6]

Interaction between Radio-Waves?

THE coming into operation of the Luxembourg high-power broadcasting-station on a wave-length of 1190 m. has caused the following remarkable phenomenon. For the first time on April 10 of this year it was observed at Eindhoven, Holland, that when a radio-receiver was tuned to Beromünster (460 m.), the modulation of the Luxembourg station could be heard on the background to such an intensity that during the weak passages of the programme of Beromünster the programme of Luxembourg was heard with an annoying strength. Since the field-strength of Luxembourg at Eindhoven has the quite normal value of about 10 mv./m. (the distance from Luxembourg to Eindhoven is somewhat more than 200 km.) and the same phenomenon was observed with different types of receivers, this cannot be due to cross-modulation in the receivers. It was also observed with a battery set away from the electric distribution system of the town, so that any disturbing influences from these sources were eliminated. Hence it seems that the phenomenon has its origin somewhere in the transmission between Beromünster and Eindhoven. It may be remarked that Luxembourg is situated nearly on the line joining Beromünster and Eindhoven.

Since the first observation the same phenomenon has been observed at Eindhoven with different intensities on Radio Paris (1725 m.), Budapest (550 m.), Munich (533 m.), Lyons la Doua (466 m.), Sottens (404 m.), Mühlacker (361 m.), Strasbourg (345 m.), Milan (332 m.), Poste Parisien (328 m.) and Frankfurt (259 m.), which all lie somewhat in the direction from Eindhoven to Luxembourg and at a greater distance from Eindhoven than Luxembourg. It has also been observed on Beromünster at Rotterdam, near Arnhem and at Düsseldorf. It was always the modulation of Luxembourg which could be heard on the background. This modulation has not been observed on Langenberg (472 m.) and Brussels (509 m., 338 m.), or on a British station.

Kinetics of the Iodine-Oxalate Reaction

SINCE 1916, when one of us[1] reported that this reaction is very sensitive to light and that the dark reaction has a high temperature coefficient, a large amount of work has been carried out on this chemical change by several chemists[2].

The majority of workers believe that the velocity of this reaction in light is not directly proportional to the light intensity but varies as the square root of the intensity of the incident radiation, although Bhattacharya and Dhar[3] have observed that by using an aqueous solution of iodine in the absence of potassium iodide, the relation between velocity and light intensity for this reaction approaches unity in radiations of mean wave-lengths 5650 A. and 7304 A.

We have carried out further experiments on this reaction using normal potassium oxalate and $N/850$ aqueous solution of iodine without the addition of potassium iodide, and some of the results are as follows:

	Dark	8750 A.	8500 A.	3340 A.	3512 A.	3452 A.	3125 A.	3536A.
$k_{28^\circ}/k_{18^\circ}$	4·64	3·92	3·54	2·02	2·25	2·38	2·38	2·44

When potassium iodide ($N/277$) was added to the reaction mixture, the velocity was greatly diminished and $k_{32^\circ}/k_{22^\circ}$ assumed the high value 8·84 in the dark.

In the absence of potassium iodide and with normal oxalate and $N/850$ iodine, the following results were obtained for the relation between light intensity and velocity:

Wave-length in A.	Observed ratios of velocities	Ratio of light intensity
3500	1·32	4
3340	1·79	4
3536	3·25	6·25
8500	3·97	4·34
8750	2·71	2·44

It appears that the relation between the velocity and light intensity varies from 1/3 to 5/4 approximately. Several other photochemical reactions taking place in aqueous solutions behave in a similar manner. It is now well known that the photochemical reactions between chlorine and hydrogen and bromine and hydrogen in the gaseous state are proportional to the square root of the light intensity under certain conditions and are directly proportional to the light intensity under other conditions. We have shown experimentally and theoretically that the relation between the velocity and the light intensity (or the amount of absorbed light) in a photochemical change is not constant but changes with the acceleration of the reaction by light absorption[4].

Ultra-Violet Bands of Oxide of Phosphorus

THE Phosphorus arc in air gives out a band spectrum in the ultra-violet, which is attributed to the PO molecule. The vibrational quantum analysis of these bands has been previously done by one of the authors[1]. The rotational structure analysis of the (0, 0) band at λ 2477·80 shows that it consists of six main branches, namely, $P_1\ Q_1\ R_1$ and $P_2\ Q_2\ R_2$ and two other faint satellite branches. For low quantum numbers, the satellite branches ${}^{R}Q_{21}$, ${}^{Q}P_{21}$, ${}^{P}Q_{12}$ and ${}^{Q}R_{12}$ are superposed on the main branches. The intensity of the lines of the different branches satisfy the criterion of a ${}^2\Sigma \rightarrow {}^2\pi$ transition. The band structure is analogous to the ν-bands of NO_1 as is anticipated from theoretical considerations. The following molecular constants (cm.$^{-1}$ units) have been obtained.

$$\nu'_e = 1{\cdot}416 \times 10^{3} \qquad \nu''_e = 1{\cdot}458 \times 10^{3}$$

$$B'_e = 1{\cdot}3060 \qquad B''_{e\,(\frac{\pi}{2})} = 1{\cdot}2332;\ B''_e\,({}^{2}\tfrac{\pi}{2}) = 1{\cdot}2256$$

$$D'_e = -4{\cdot}60 \times 10^{-6} \qquad D''_{e\,(\frac{\pi}{2})} = -4{\cdot}96 \times 10^{-6};$$

$$D''_{e\,({}^{2}\frac{\pi}{2})} = -4{\cdot}86 \times 10^{6}$$

$$\alpha' = \alpha'' = 0{\cdot}0073$$

The detailed results will be published elsewhere.

Conductivity of Mixtures of Gases

IT is well known that the electrical conductivity of certain gases may be greatly increased by the addition of very small quantities of other gases. For example, the electrical conductivity of pure helium is greatly improved by the addition of 0·01 per cent of pure argon. In gases, the electrical conductivity in uniform fields between parallel plates depends upon the ratio X/p, where X is the electrical intensity in volts per centimetre, and p is the pressure in millimetres of mercury, and is a maximum for a certain value of X/p depending upon the nature of the gas. The photo-electric currents obtained with a constant force between parallel plates at different distances apart are represented by the ordinates of the curves, Fig. 1, and the potential differences between the plates by the abscissæ. The three curves give the currents in pure helium, in pure argon and in helium containing 0·025 per cent of argon. The values of the ratio X/p were, 50 in pure helium, 200 in pure argon and 15 in the mixture. Under these conditions the rate of increase of the current with the distance between the plates was a maximum.

Two theories have been advanced to account for the increase in conductivity of the mixture, namely, the action of direct collisions of electrons with the atoms of argon, and the action of metastable atoms of helium which are formed by electron collisions with helium atoms. These metastable atoms of helium may be formed when the electrons attain an energy corresponding to approximately 20 volts. It is then supposed that the metastable atoms of helium ionise the atoms of argon, which require an energy corresponding to approximately 16 volts. There is much controversy concerning the relative importance of these two processes. For example, Penning[1] states that the increase in conductivity may be attributed entirely to metastable atoms, whereas Townsend and McCallum[2] have pointed out that the effect of direct collisions of electrons may be considerable in these circumstances.

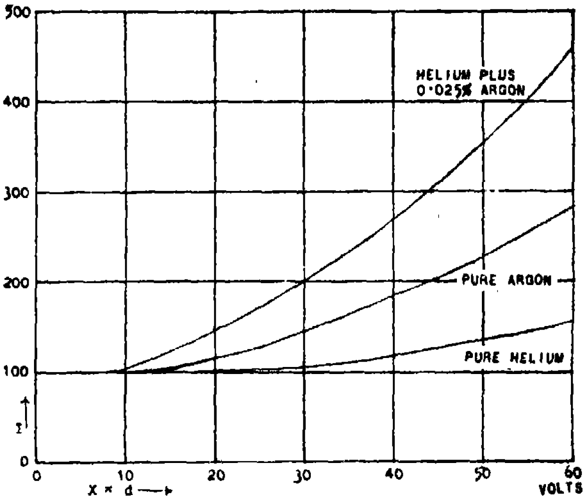

FIG. 1.—Conductivity between parallel plates. *I*, current between plates in arbitrary units; *X*, forces between plates in volts per centimetre; *d*, distance between plates in centimetres.

The results given in Fig. 1 are of importance in showing that a large number of new ions are formed in the mixture of 0·025 per cent of argon in helium when the potential between the plates is increased from 9 volts to 18 volts, the distance between them being adjusted so as to maintain a constant force. As no metastable atoms of helium could be formed until the electrons attained an energy of 20 volts, the increase in conductivity in these circumstances must be attributed to the direct collisions of electrons with argon atoms. It would not appear from the curve that any important new process occurs when the potential between the plates exceeds 20 volts, such as might be attributed to the action of metastable atoms.

More complete results will shortly be published elsewhere.

Determination of Crystal Lattice Constants by Electron Diffraction

THE accuracy of the determination of crystal lattice constants by electron diffraction has hitherto been limited by various sources of error, chief of which is that due to the lack of precision attendant upon the measurement of high voltages. We have recently succeeded in eliminating this and other sources of error in the following manner:

A double specimen, mounted as required either for transmission or reflection, is employed. One half consists of a substance the lattice constants of which are known, having been determined by exact X-ray analysis; the other half of the specimen consists of the substance of unknown lattice constants. The shutter of the diffraction camera is in two halves each capable of independent operation. The electron beam penetrates or impinges upon one half of the specimen and the corresponding electron diffraction pattern is recorded upon one half of the photographic plate. Thereupon the specimen is either traversed through the beam or rotated in the azimuthal plane, thus bringing the second half of the specimen under examination. The hitherto unexposed half of the photographic plate is now exposed. The accompanying reproduction (Fig. 1) of a transmission photograph obtained in the manner outlined above will serve to make clear the principle underlying the method, which is analogous to the use of the iron-arc reference in spectroscopy.

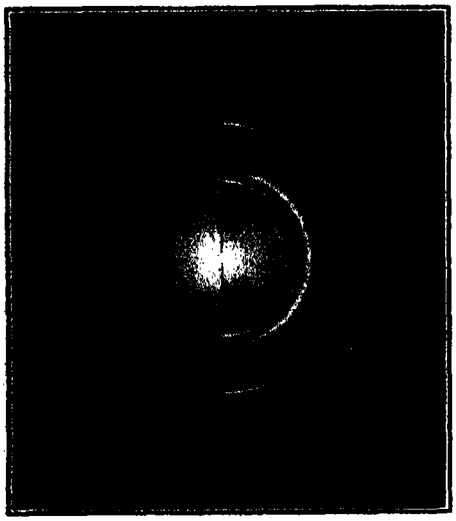

FIG. 1.

A more detailed account of this method will be published shortly.

Selective Lattice Distortion in Wires under Torsion

X-RAY analysis of metals affords a means of detecting the type of internal strain which is accompanied by distortion of the crystal lattice. The distortion is reflected in the X-ray diffraction photographs in that it causes a broadening of the spectrum lines; the effect has been noted for metals which have been cold-worked or which contain a highly dispersed solute.

I find that lattice distortion is produced also in wire (copper, nickel) under torsion, and a point of particular interest appears. Since torsional stress can be applied gradually, the rate of broadening of lines from different planes can be compared. It is found first, that the (420) planes distort more rapidly than do the (331); and, secondly, the lines do not broaden continuously with increasing stress, but exhibit instead alternating periods in which their definition is partially recovered.

The selective distortion of the planes is of such an order that the (331) $K\alpha_1\alpha_2$ doublet is easily discernible after the (420) doublet has diffused into a single broad line. The recovery effect is most marked on the (331) line; the doublet diffuses and reappears, though to a less and less degree, as the torsion of the wire is increased.

The observations implement the view that lattice distortion grows, as stress is applied, to the maximum characteristic of the metal; that the more highly distorted grains disrupt, and then tend to re-crystallise, presumably adopting a more convenient orientation, in a temporarily less distorted state. The latter stage would coincide with the recovered definition of particular lines.

Extension of the Visible Absorption System of NO_2 to Longer Wave-Lengths

IN two recent letters to NATURE, Cassie and Bailey[1] as well as Harris, Benedict and King[2] report new investigations of the infra-red and ultra-violet absorption spectrum of NO_2. We should like to remark that we have recently made new investigations of the *visible* absorption system of NO_2 which, as is well known, is extremely complicated. In consequence of this, neither its vibrational nor rotational structure has as yet been analysed. A possible explanation for this complicated structure is that, in consequence of the Franck-Condon principle, chiefly the higher vibrational levels in the upper state are excited.

On this assumption it was to be expected that the system would extend to longer wave-lengths with sufficient absorbing length and there become more simple. This proved in fact to be the case. We have found a rather simple series of bands starting at about 8900 A. and extending to shorter wave-lengths. The distance between the main bands is about 740–730 cm.$^{-1}$. This must be a vibrational frequency of the upper state.

We are engaged now in the investigation of these new bands with longer absorbing layers and with high resolution. On account of the absence of overlapping of different bands in the region now being investigated, it seems very likely that it will be possible to analyse the vibrational and rotational structure.

Social Organisation and Marriage in Madagascar. An account of the culture of the Tanala, a group living on the southern third of the eastern massif of Madagascar, which was visited by the Marshall Field expedition to Madagascar, 1926, has been prepared by Mr. Ralph Linton (Pub. 317, Anthrop. Ser., 22, Field Mus. Nat. Hist.). The Tanala live at the meeting point of four fairly distinct cultures. They are, and would appear to have been always, an agglomeration of groups, of which the composition was continually changing. Yet their culture is fairly uniform in its details, and in comparison with that of the rest of Madagascar, relatively simple and archaic. The social organisation, as in other groups of Madagascar, is based on a combination of two factors, common descent and common residence. Next to the family, the smallest group is the lineage, a local group of relatives, who claim descent from a common ancestor in the male line. Next comes the gens and then the tribe, the latter not necessarily an organic unit, but often a group of gentes brought together by conquest or alliance. The family consists of the man, his wife, or wives, and their children, the father in theory being absolute, not only over his own children, but over his son's children as well. In one of the two main divisions, the Ikongo, however, the mother has authority over the children, while control of the property is vested in the father. Marriage between different generations, or within the lineage is undesirable, and formerly there was a strong feeling in favour of marriage within the village. The Ikongo, however, in their fear of incest, favour marriage outside the village. Relationship affecting marriage is reckoned by blood, marriage and 'blood-brotherhood'. Among the Menabe marriage between the descendants of two sisters traced in the female line is absolutely forbidden. Cross cousins are urged to marry and marriage of cross cousins in the second generation is considered the most desirable form of union. The bride-price legalises the union. It is not returnable, except among the cattle tribes, and even there only in theory and not commonly in practice, as it determines the rights in the children.

'Western Indian' Art. An interesting document relating to the comparatively little-known Jains has been edited by Prof. W. Norman Brown, professor of Sanskrit in the University of Pennsylvania, and published by the Freer Art Gallery of the Smithsonian Institution, Washington (Oriental Studies, No. 1). The manuscript, which was purchased by Prof. Brown at Benares in 1922, is in folio, written in gold ink on a specially prepared background of red, black or blue, and illustrated with seven primitive paintings in brilliant colouring and of skilled draughtsmanship. It deals with the story of the monk Kalaka, one of the saints of the Jain cult, a pseudo-historical figure. Apart from the historic and religious interest of Jain manuscripts, they are of importance for the history of Indian art, an aspect which, virtually, has been neglected. They form a school, for which Dr. Brown suggests the name 'Western Indian', which preceded and on the Indian side was the parent of Moghul and Rajput art. The school lasted from the beginning of the twelfth to the seventeenth century. A peculiar characteristic of the school in drawing is the externalisation of the second eye in the representation of the profile, a feature also found, Dr. Brown notes, in paintings at Pagan in Burma. Dr. Brown thinks that among the Jains it is an attempt to represent the protruding glass eyes of the stone figures in Jain temples. It may be pointed out, however, that externalisation of the eye is a common feature in primitive drawings. If this were indeed a primitive feature, it would not be the only primitive convention surviving in Indian art.

Life-History of *Calanus finmarchicus*. During the year 1931–32, the work of the staff of the Scottish Marine Biological Association's station at Millport has been concentrated mainly on the copepod *Calanus finmarchicus*, one of the chief foods of the herring and also an important constituent of the food of young fishes of other species (Scottish Marine Biological Association: Annual Report, 1931–32. Pp. 1–24. Glasgow: 185 St. Vincent Street). As the result of well-regulated team work, the complete life-history of this copepod crustacean is being pieced together, and the physical, chemical and other conditions which determine its abundance slowly but surely ascertained and recorded. After an incubation period of about twenty-four hours, *Calanus* hatches out from the egg as a nauplius larva. This nauplius then moults through five more nauplius stages, after which it enters into a kind of intermediate or pre-adult phase known as the first copepodite stage. There are, in all, six copepodite stages, of which the last is the true adult. *Calanus* stops breeding in the autumn, most of the population which exists through the autumn and early winter being pre-adults of stage 5. During this resting season the total numbers show a steady decrease, so that very few *Calanus* are present when eventually moulting into the final adult form begins. Males appear first and females predominate later. Eggs are then laid and the brood produced develops quickly, producing full adults in about a month. By this time the parent (autumn) brood has entirely died out. The size of the *Calanus* remains the same throughout the autumn, but the winter brood consists of much larger animals. In addition to these studies of the *Calanus* population as a whole, detailed laboratory work is also being carried out on the digestive, respiratory, and other physiological activities of these animals.

The Arachnid Group, Opiliones-Laniatores. Dr. W. Sørensen, who died in 1916, left a number of descriptions of species of harvesters, and notes on their families and genera, which would have formed part of his proposed monograph on the sub-order Laniatores of the Opiliones. These manuscripts have been revised, first by Dr. C. With and latterly by Dr. K. L. Henriksen, and are now published (*Kong. Danske Vidensk. Selsk. Skr.*, 9, iii, 4, pp. 199–422) as a memorial to the extensive work done by Sørensen on these Arachnida. In Prof. C. F. Roewer's classification, the Laniatores were divided into six families, with thirty-two sub-families. The present work covers five of these families, but arranges them in five super-families and fourteen families. Three of these families are new; twenty new genera are also established and many new species from all parts of the world are described. All diagnoses are in Latin and the editor's notes are in English. These give the history of the specimens examined and make clear the relationship between the systems of Sørensen and Roewer. The work is of considerable interest as a supplement to Roewer's great volume, "Die Weberknechte der Erde", 1923, and a fitting tribute to the memory of its author.

Disinfection of Glasshouses with Sulphur. Burning sulphur as a means of disinfecting vacant glasshouses has been found liable to result in a serious type of damage to a subsequent chrysanthemum crop (*J. Min. Agric.*, 39, 1085). The injury, which has frequently been encountered by growers, could not be traced to any fungal, bacterial or insect pest and had hitherto remained beyond control. Investigations by W. H. Read and O. B. Orchard of the Cheshunt Research Station, however, have shown that the scorching and wilting of the plants is due to zinc sulphate, formed on the overhead galvanised wires and painted surfaces and conveyed to the plants in drops of condensation water. Confirmation of the cause of damage was obtained by the production of similar injury when solutions of zinc sulphate were applied directly to the plants, 1 part of the salt in 300 of water being the maximum amount tolerated without visible injury resulting. No trouble was experienced if a lead or barium paint were substituted for 'zinc white' or if the atmosphere were kept very dry, but prevention of damage by means of these alternatives has obvious disadvantages. In the event of burning sulphur having already been used as a disinfectant, the possibility of damage can be greatly minimised if the house is thoroughly hosed down with water at frequent intervals. The substitution of another type of fumigant such as naphthalene or formaldehyde is, however, to be preferred. The use of sulphur as a dusting powder, on the other hand, is quite a safe procedure, as it is only when burnt that the formation of zinc sulphate takes place.

Disintegrating Action of Roots of Trees. In *Current Science* (Vol. 1, No. 3, 78, Sept. 1932) a brief account was published of the work of Mr. Mohammad A. R. Khan, principal of Osmania University College, on the "Disintegration of Igneous Rocks due to the Action of the Roots of Certain Rock-loving Plants", the observations having been made in the Deccan. The species more specifically referred to were *Carissa carandus*, *Gymnosporia montana*, *Butea frondosa* and *Anona squamosa*. A communication to NATURE, which we are unable to print in full, reports further investigations of this phenomenon. Mr. Khan attributes the extraordinary positions taken by the fantastically rounded igneous rocks of the Deccan in large part to the action of the roots of certain trees. Amongst these he considers that *Gymnosporia montana*, which is found for hundreds of miles in the rocky districts round about the city of Hyderabad, is the most formidable rock-disintegrator. It is well known that the roots of plants and trees exert an enormous influence in breaking up rocky strata beneath the surface of the superimposed soil layers; and that this is accomplished by the finer rootlets penetrating into tiny crevices and, through their subsequent growth in diameter, disintegrating the previously homogeneous mass. It is perhaps not so commonly appreciated that this action proceeds at a much more rapid pace in tropical countries, owing to the greater heat and moisture conditions. But Mr. Khan's observations would appear to show that the vegetation and the masses of smaller rootlets, which form a kind of lacework over the bases of the individual rock pieces of the curious Deccan formation, play a larger part in the disintegration and break up of the surface rocks than may have been so far attributed to it. "Where," he says, "the rocks are in contact with the soil (already formed) and the fine root-hairs of these plants have reached them, they (the root-hairs) enter the cracks and gradually draw upon the felspars and ferro-magnesium silicates for food. . . . These root-hairs spread over the rocks and permeate into the rocky material far and wide . . . producing a specific disintegration".

Spectrograph for Study of Fibrous Substances. Messrs. Adam Hilger, Ltd., have recently added to their X-ray diffraction apparatus a spectrograph constructed for the study of such fibrous substances as cotton-wool or silk. It is designed by Mr. W. T. Astbury of the University of Leeds, whose experience in such work is such as to ensure its construction on practical lines. The spectrograph proper is simple and follows orthodox lines. It consists of a collimator of variable aperture, specimen and plate holders mounted rigidly on a graduated triangular steel bar. A sector mounted on the plate holder enables photographs from the same fibre under different conditions or from different fibres to be obtained on the same plate and thus facilitates the detection of any change in lattice size. In such an apparatus the accessories are most important and the new spectrograph is very fully equipped in this respect. Among the fittings supplied with it are frames for mounting fibres in different positions relative to the X-ray beam and under different conditions of tension. Attachments are also provided to enable fibres to be studied under varying humidity conditions and during treatment with steam or acids. The apparatus is essentially practical and should have important applications.

Hyperfine Structure and Nuclear Moments. In *Current Science* (vol. 1, pp. 264 and 303, 1933) Prof. B. Venkatesachar and L. Sibaiya give the nuclear spins of zinc (½), caesium (5/2) and sodium (½) as obtained from hyperfine structure observations with the use of Lummer plates and a new type of source. The experimental value given for zinc has been deduced by a somewhat arbitrary selection of some of the reported components, and differs from the value 3/2 given by Schüler and Westmeyer (*Z. Phys.*, 81, 565; 1933). The intensities of the observed components, however, are not even in approximate agreement with the known abundance percentage of the odd isotope, and it seems quite probable that the observations were affected by ghosts or self-reversals. The values given for caesium and sodium [illegible] obtained from intensity measurements of [illegible] resonance lines, and are not in agreement with [illegible] based on a more rigorous analysis. The spins of the alkali metals are discussed in relation to a theory of nuclear spins previously proposed by Venkatesachar and Subbaraya (NATURE, 131, 552, April 15, 1933), but this discussion is based on early results now known to be inaccurate, and adds nothing to the known facts. An elaboration is made of Venkatesachar and Subbaraya's theory which predicts the spins for most of the elements of the periodic table. A critical examination of the theory, however, suggests that agreements between predicted and observed values are fortuitous, arising largely because for most elements a whole regular series of alternative values is given, the observed value naturally agreeing with one of these. It follows that the predicted value for cæsium (5/2) carries no weight.

Analysis of Cast Iron. The British Cast Iron Research Association has recently published a monograph on "Recommended Methods for Sampling and Analysis of Cast Ferrous Metals and Alloys" (Special Publication No. 1. Pp. 44. *Birmingham.* 10*s.* 6*d.*), which will be found of great value by all who have to deal with cast iron and its uses in industry. The analysis of cast iron presents difficulties of its own, which begin with the sampling, special care being necessary in order to ensure that the quantity taken for analysis is representative of the composition of the metal. The precautions which should be taken are well described. Owing to the increasing use of alloy cast irons, where increased strength or resistance to chemical attack or to oxidation at high temperatures is required, the analyst must be prepared to look for elements other than those found in ordinary pig iron, including nickel, chromium, aluminium, copper, cobalt, molybdenum, tungsten, vanadium and titanium, and the analytical methods become correspondingly complex. The procedures here described are those which have proved themselves in the course of the life of the Association, during which the staff has had to conduct the analyses needed in the course of the research work undertaken at the laboratories in Birmingham, as well as those demanded by members. They may therefore be regarded as authoritative. The methods are clearly described, and with only sufficient detail for the guidance of competent analysts. Some useful hints, such as a reference to the presence of manganese in asbestos wool used for filtration, are to be found in the text. A closing section is concerned with the polishing and etching of specimens for microscopical examination. This might be improved in some details. Recent American workers have shown how slight modifications of technique greatly increase the truth of rendering of the graphitic constituents. White metal for embedding irregular specimens is greatly inferior to bakelite in powder form, which has no electrolytic action and is easily applied.

Astronomical Topics

A Star occulted by Jupiter. Mr. A. Burnet has for some years predicted occultations of stars by the planets. He lately predicted the occultation of the ninth magnitude star B.D. 8°, 2456 by Jupiter, which was visible in the United States on the night April 20–21. A Science Service bulletin of April 29 reports that the phenomenon was observed and photographed at the Yerkes Observatory. The director, Prof. O. Struve, sent copies of the photographs to Science Service. It is stated that they show the approach of the star to the planet; on the last photograph it is nearly in contact with the limb. The four large satellites also appear on the photographs. Planetary occultations of stars are not very common. On one occasion a sixth magnitude star was occulted by Jupiter, and with the large reflector at Melbourne the star remained visible for some distance within the limb of the planet. Stars have also been seen to remain visible when passing behind Saturn's ring.

Recent Observations of Mars. The March issue of the *Journal of the British Astronomical Association* contains a preliminary report of the work of the Mars Section, by its director, Dr. R. L. Waterfield. Midsummer of the northern hemisphere occurred on April 10; rapid shrinking of the north polar cap occurred; Olympia became separated from the cap on March 12, and Lacus Hyperboreas appeared as a dark spot on the snow-line on March 22. Another rift across the cap was seen at the end of March in longitude 300°. The northern maria, Casius, Propontis and Acidalium were very dark. The southern maria were pale, presumably owing to mist over them. The two bright bridges across Acidalium, known as Baltia and Achillis Pons, were very bright, as was also Herculis Pons. Margaritifer Sinus was shorter than usual, and had a blunt north end, instead of the usual point. Solis Lacus, which changes much in appearance at different oppositions, was small, pale and difficult to see. The canals Ganges, Euphrates, Hiddekel and Gehon were not seen early in the apparition, but reappeared at the end of March. A sketch by Mr. Hargreaves shows Nilokeras doubled.

Comets. Circulars from New Zealand appear to indicate that the comet Dodwell-Forbes was independently discovered there; the name of the discoverer is not stated. It was at first suspected to be Tempel's comet of 1866, but this was soon disproved by its motion. It is, however, moving in an elliptical orbit; the two following orbits have been recently published, based on an arc nearly two months long: the equinox is that of 1933·0.

T	1932 Dec. 30. 52167 U.T.	Dec. 30. 51633 U.T.
ω	327° 20′ 4·2″	327° 19′ 40·8″
Ω	77 40 21·7	77 38 54·5
i	24 30 3·6	24 30 33·0
e	0·972064	0·973560
q	1·130720	1·131018
Period	257·5 years	279·9 years
Computer	H. Hirose	A. D. Maxwell
Reference	*U.A.I.Circ.* 429	*Pop. Astr.*, March

Peltier's comet shows no deviation from a parabola; the following orbit was derived by Mr. Möller from observations up to February 28, and satisfies observations made a fortnight later (*U.A.I. Circ.* 428):

$$\begin{array}{ll} \mathrm{T} & 1933\ \text{Feb. } 6.\ 689\ \text{U.T.} \\ \left.\begin{array}{ll} \omega & 135^\circ\ 58'\ 41'' \\ \Omega & 311\ \ 31\ \ 51 \\ i & \ 86\ \ 40\ \ \ 5 \end{array}\right\} & 1933{\cdot}0 \\ q & 1{\cdot}00060 \end{array}$$

Comet Schwassmann-Wachmann is now in aphelion; it passed perihelion on 1925 May 15, two years before its discovery; its period is 16·3 years, so aphelion passage will be early next July. In spite of its great distance it is still showing activity; a remarkable brightening up at the end of last year was noted both at Bergedorf and at Yerkes. It is probably more massive than most comets.

Recent Developments in Coal-Mining Explosives

IN British mines, about thirty million pounds weight of explosives are used annually. This involves the firing of about sixty million shots. When any shot is fired there is potential danger, particularly in gassy mines. Recent improvements in coal-mining explosives have aimed at increasing both their safety and efficiency. The three main developments have been (1) low-freezing explosives, (2) low-density explosives, and (3) 'Cardox'.

In a paper read recently before the Midland Institute of Mining Engineers, Dr. W. Payman, chief chemist to the Explosives in Mines Research Committee, discusses these developments. Nitro-glycerine freezes at 13° C. (55° F.) so that during storage in cold weather all explosives containing it become solid. Consequently many attempts have been made to render nitro-glycerine explosives non-freezing. The first method adopted in Great Britain was the substitution of a portion of the glycerine used in the manufacture of nitro-glycerine by polyglycerine. Though quite effective, this has now been replaced entirely by nitro-glycol. Polyglycerine was difficult to make and was not of constant composition. Glycol resembles glycerine in many respects and is largely used for preventing freezing in motor-car radiators. The efficacy of the use of low-freezing explosives is indicated by the fact that no fatal accident due to handling hard or frozen explosives has been reported for several years.

Low-density explosives have been developed mainly to reduce the shattering effect of high explosives and to increase the yield of lump coal. The average density of the new low-density explosives is about 0·7, whereas that of the older explosives is 1·0; their respective weight-strengths, however, as judged by Government tests, are about the same. The decrease in density has been brought about by the incorporation with the explosive of bulky wood sawdust or plant fibre. The reduced shattering effect of the low-density explosive appears to be due mainly to the spreading of the direct action of the explosive on the coal.

The introduction of 'Cardox' is one of the outstanding contributions to safety of recent years. The 'Cardox' blasting device consists of a strong steel shell containing a charge of liquid carbon dioxide and a heating element which converts the liquid carbon dioxide almost instantaneously into gas at high pressure. The pressure produced is sufficient to shear a disc at one end of the shell or cartridge, when the gas escapes and exerts a disruptive effect on the surrounding strata. The advantages claimed for the 'Cardox' blasting device are: (1) increased safety in the presence of firedamp and in handling; (2) increased yield of lump coal; (3) easy recovery of misfires; (4) little disturbing effect on roof near the shot-hole; and (5) absence of fumes.

It is encouraging to learn that the merits of the 'Lemaire sheath' are at last being given the serious attention of the Safety in Mines Research Board. This safety device consists of a thin cylinder of plastic clay mixed with sodium fluoride or another agent or both; the clay cylinder or 'sheath' envelops the explosive and largely damps out the flame resulting from its detonation. The Lemaire 'safety sheath' has been officially adopted in Belgium for many years.

Radio Direction-Finding

AT a meeting of the Wireless Section of the Institution of Electrical Engineers held on April 5, two papers were read describing recent research carried out at H.M. Signal School in the development of radio direction-finders for use in naval ships. In the usual form of direction-finder, it is customary to employ a figure-of-eight reception characteristic for taking the direction, and then, by a separate operation, to resolve the 180° ambiguity by determining the 'sense' of the bearing previously obtained. The ordinary cardioid reception characteristic employed for the latter operation is not suitable for determining the bearing to any great accuracy, so that the two operations are necessary, involving an increase in the time required to obtain a bearing.

In one of the papers, entitled "A Radio Compass Developed in H.M. Signal School", Messrs. C. E. Horton and C. Crampton described a system whereby both the direction and the sense are determined by a single operation. The system employs two rotating loops or frame coils fixed together at right angles; one loop is arranged to give a figure-of-eight characteristic while the other gives a cardioid, the two characteristics being combined in such a way that the minimum of the cardioid is coincident in direction with one zero of the figure-of-eight. The paper included an analysis of the behaviour of such a direction-finding system, when installed in a steel ship, and also an account of experiments carried out to verify the results. It was shown that by a suitable arrangement of the circuits the errors in bearing due to currents set up in the ship itself can be reduced to the values obtained with the equivalent simple direction-finder in the same position.

The second paper, by Mr. J. F. Coales, comprised a calculation, with subsequent experimental measurement, of the magnitude of the errors experienced on a ship's direction-finder due to the shape and orientation of the aerial at the transmitting station. The experiments were carried out in a light cruiser, with a destroyer as the transmitting ship. The aerial on the latter was of the inverted 'L' type, and errors of 1° or 2° were found in the calibration of the direction-finder, when the receiving ship was not in line with the horizontal portion of the transmitting aerial. This error decreased rapidly with increasing distance between the two ships, becoming negligible at about four miles. A knowledge of this error is important in carrying out a calibration of the direction-finder at very short distances, and it is desirable to take two sets of readings, with the transmitting ship steaming round the receiving ship, first in a clockwise, and then in an anticlockwise direction. The mean of the readings so obtained will form a true calibration of the direction-finder for signals arriving from a distance.

Investigations on Timber

UNDER the auspices of the Department of Scientific and Industrial Research, the report of the Forest Products Research Board for the Year 1931 has been issued. It is combined with the report of the Director of Forest Products Research for the same year.

The investigations carried on during the year fall roughly into three groups: (1) the dry rot investigations being carried out in the new experimental building erected for the study of this subject, (2) investigations into the death-watch beetle and into the damage caused by the *Lyctus* powder-post beetles, and (3) investigation work on Empire timbers, more especially in the tropical hardwoods. Under (3), the report of the Research Board has some pertinent remarks on the subject of encouraging and organising the placing of Empire tropical timbers on the markets. Several of the points discussed have been already alluded to in NATURE (129, 696, May 7, 1932).

The report describes improvements in the design of seasoning kilns, new apparatus for the determination of humidity in the kilns, and a method of employing the photoelectric cell in the study of wood structure by using it to measure the percentage of empty space in the interstices of a timber due to its cell structure. Apparatus is also described which determines the gloss of a machined surface by measuring the amount of light scattered or reflected from it. Another instrument measures the finish on a surface by recording the frictional resistance experienced by dragging a standard metal plate over the surface.

The report emphasises the importance of research on wood-working tools. "A new Empire timber is often condemned by the machinist as 'unworkable' simply because machines, developed to deal with timbers in common use, are not suited to the very different structure of the new timber. A modification of feed speed, cutting speed or cutting angle may be all that is necessary to make the most obdurate timber workable, but in order to foretell these modifications a knowledge of the way in which the cutting action of any tool, whether plane, saw or drill, should be related to the structure of the wood on which it is to work is essential."

During the year, 689 specimens of structural timber were tested, while 3,470 test pieces cut from a material free from knots, etc., were submitted to almost every conceivable mechanical test. Tests on physical properties, etc., numbered more than 9,500. A total of 4,800 specimens treated in various ways with eight wood preservatives, including low temperature tar and its distillates, have been exposed for test and are kept under constant observation.

Antarctic Geology and Glaciation [*]

THE sub-antarctic islands south of the Indian Ocean—Prince Edward and Marion Islands, the Crozet Islands, St. Paul and Amsterdam Islands, the Kerguelen Archipelago, and Heard Island—are all of the character of oceanic islands. So also is Macquarie Island in the Australian sub-antarctic. They are the summits of vast igneous extrusions heaped upon the sea floor. Volcanic activity has ceased only in recent times. Hot springs are still met with at St. Paul and have been vaguely reported from Kerguelen Island. All those islands in higher latitudes than 40° S. show evidence of severe glaciation during geologically recent times. Glaciers are still a feature of Kerguelen Island, Heard Island, and the Crozets. As a consequence, morainic debris, fluvial sands, and peat beds occur irregularly distributed over their surface.

Magmas contributing to the formation of these islands are, in the main, very basic. Varieties of peridotite, basanite, and basalt have been extruded on a vast scale. Next in order of abundance but subordinate in quality is an interesting range of trachytes and phonolites. Coarse tuff beds on Macquarie Island, Heard Island, and Kerguelen contain fragments of a dense, recrystallised *Globigerina* ooze, indicating that the igneous outbursts have broken through pelagic sediments. The occurrence of unsaturated magmas amongst the volcanic effusions may be attributable to the assimilation of quantities of such calcareous oozes.

Acid lavas are scarce, the only notable record so far being the appearance of rhyolite amongst the earlier eruptive debris of St. Paul Island.

Macquarie Island is unique amongst these localities in exhibiting some of its basic igneous rocks in an advanced state of serpentinisation. There, also, are found former submarine volcanic centres where tachylite now considerably palagonitised was extruded.

Kerguelen, which is much larger than any of the other islands under consideration, also reveals a more complicated geological structure. This appears in the deep fjords, where sections are exhibited cut down through several thousand feet of strata. In the south-western portion of the island, there are thus brought to light plutonic rocks such as monzonite, mica-diorite, and even syenitic types. These have doubtless originated, as Lacroix has explained, by injection into the already solidified effusive lava system.

Chronological evidence is limited and is so far found only at Kerguelen. There, a land surface composed of igneous rocks, basalts, trachytes, and the like, appears to have been in existence in early Tertiary times. Upon this surface, fluviatile conglomerates were laid down on a grand scale. These incorporate in their upper limits irregular intercalations of lignite. The fossil vegetation recorded is dominated by an Araucarian flora very similar to that existing to-day in the considerably warmer climate of Norfolk Island. The age of this lignite is likely to be late Oligocene.

Thereafter follows a vast succession of basalt flows and ash beds, high up in which series has been located a band of coarse littoral sediment rich in fossil mollusca with a Pliocene facies. The mollusca, by their nature, indicate water warmer than prevails to-day along those shores. Further volcanic outpourings both basic and trachytic conclude the series.

---

[*] Substance of a lecture entitled "Geology and Glaciation of some Islands of the Southern Ocean and the newly discovered Antarctic Mainland" delivered by Sir Douglas Mawson at the Geological Society of London on May 10.

Then came the glacial period. Almost the entire land area became buried under ice. Only now is Kerguelen emerging from a period of profound glaciation, which re-moulded pre-glacial topography and has yielded an outstanding example of fjord and skerry development.

To turn now to the antarctic regions nearer the pole. It has been shown that southward of Australia and the Indian Ocean there exists a continuous, circumpolar, continental bulge. This has been delineated in the neighbourhood of the antarctic circle through 3,000 miles of arc. Thus, for the first time, it is demonstrated that under the antarctic ice there lies a continent and not merely scattered islands holding together an ice mass. Everywhere around this great sector the rocks outcrop on the coast; also those ice-borne from the land and shed on the sea floor are continental in type. The antarctic land south of the Indian Ocean is characterised by rock forms typical of the deeper continental sub-strata, such as varieties of granite, norite, and charnockite; also gneisses and schists in which garnet, cordierite, and sillimanite figure abundantly.

Though most of this land region is smothered beneath an ice cap, continental in dimensions, yet there is clear evidence that the intensity of glaciation has greatly diminished since the peak period. There seems no reason to doubt that the latter coincided with the ice flood of the Pleistocene, recorded in the northern hemisphere. At the height of the glaciation, the continental ice cap extended everywhere to the margin of the continental shelf which, in the antarctic, is still unduly depressed, owing apparently to lag in isostatic readjustment after subsidence under the ice load. Submarine banks found distributed along its margin and elsewhere on the continental shelf indicate standstill periods of the ice front. Rock-floored, ice-scoured, moat-like depressions are a feature between the off-lying submerged banks and the present coast.

University and Educational Intelligence

BRISTOL.—The following appointments have recently been made: Dr. J. F. Baker, to the chair of civil engineering; Prof. A. E. Trueman, professor of geology in University College, Swansea, to the chair of geology; Prof. G. Hadfield, professor of pathology in the London School of Medicine for Women, to the chair of pathology; Mr. J. W. de Witt G. Thornton, lecturer in pharmacology; Mr. J. D. A. Gray, senior pathological officer in the Department of Preventive Medicine; and Mr. J. W. Edgell, dairy bacteriologist with the standing of an assistant lecturer in the University.

CAMBRIDGE.—The following have been appointed to University lectureships: Mr. R. F. Kahn, of King's College, in the Faculty of Economics and Politics; Mr. A. H. Wilson, of Emmanuel College, Mr. W. V. D. Hodge, of St. John's College, and Mr. P. Hall, of King's College, in the Faculty of Mathematics.

A vacancy exists for a University demonstrator in the Department of Mineralogy and Petrology, who will be required to teach crystallography and crystal physics. Applications should be sent to Prof. C. E. Tilley, at the Mineralogical Laboratory.

It has been recommended that the plans prepared by Mr. Redfern for an extension of the Chemical Laboratory be approved and that the tender of £3,360 received from Messrs. Coulson and Son Ltd. for the work be accepted.

Mrs. G. Stephenson has presented to the University a valuable gift of books from the library of her late husband, Dr. J. Stephenson. Some of these books have been added to the Balfour Library and some to the library of the Advanced Laboratory of Zoology.

ST. ANDREWS.—Mr. John Anderson, surgeon in Dundee Royal Infirmary and lecturer in clinical surgery in the University, has been appointed professor of surgery in succession to the late Prof. L. T. Price.

THE Science Scholarships Committee of the Royal Commission for the Exhibition of 1851 has made the following appointments to senior studentships for 1933: on the recommendation of the University of Cambridge, Mr. E. H. F. Baldwin, for research in biochemistry; on the recommendation of the University of Edinburgh, Dr. H. W. Melville, for research in physical chemistry; on the recommendation of the Imperial College of Science and Technology, London, Mr. J. I. Armstrong, for research in plant physiology, and Dr. W. G. Penney, for research in physics; on the recommendation of the University of Oxford, Dr. B. K. Blount, for research in organic chemistry.

RURAL education in East Suffolk is in process of re-organisation along lines described in pamphlet No. 93 of the Board of Education (H.M. Stationery Office, pp. 40, 9*d*.). The new 'area' or 'senior' schools for children of 11–15 years of age, which are being set up in pursuance of a scheme prepared in 1929 for giving effect to ideals formulated in the Hadow report on the education of the adolescent, have already demonstrated how very materially their pupils may benefit, not only in the direct results of their instruction but also very obviously in health, deportment and confidence. Among salient features of the new regime is the spacious planning of the school premises. It is usual for an area school to possess or have the use of five or six acres, and this gives scope for developing "the conception of the school as a social unit, as nearly as possible a self-sufficing community, and of its site as an estate". Here is to be found the key to success in rural re-organisation; nor is it necessarily an expensive one, for the cost per place of the new schools has in no case exceeded £33. The lay-out has been left to the individual planning of the head teacher with assistance from the official organiser of gardening. Plans of a typical lay-out are appended to the pamphlet. Another important point is that the whole of the children's education is brought under one roof and under one direction. Instead of working in isolation not only from one another but also from the head teacher and class teachers, those who specialise in wood and metal work and domestic science find ample opportunities of close co-operation with the happiest results. Essential particulars are given of the arrangements for conveyance, school canteens, methods of dealing with the problem of individual differences, games and other physical activities. The pamphlet is well worth reading from cover to cover, not only by all concerned with rural education but also by all who value the welfare of rural England.

Calendar of Nature Topics

Egg-Laying and Incubation of Painted Turtle

From 1915 until 1928, J. T. Nichols collected seven records of the egg-laying of the painted turtle (*Chrysemys picta*) and these range from June 8 to July 17, the time of egg-laying in four of six cases recorded being between 4.30 and 5.30 p.m. Eggs laid about June 25, 1928, were carefully marked as to place, but were left undisturbed until it seemed very unlikely that they would emerge before spring even if by chance lack of frost permitted. On October 28 the nest was opened, disclosing 11 fully developed young turtles in a bunch with fragments of old egg-shells. They measured one to one and a half inches in shell length. It would appear that although the young of the painted turtle hatch in the autumn, they do not emerge from the ground until the following spring, differing in this respect from the young of the snapping turtle, which are to be found above ground in September.

Egg-Laying of the Leathery Turtle

The leathery turtle (*Dermochelys coriacea*), the largest of its kind, is more highly adapted for aquatic life than any other testudinate, and yet it is perhaps the most primitive of the group. Its breeding range is confined to about lat. 15° N. and 15° S. and during the months of May and June the majority of the females deposit their eggs upon some sandy shore. Leaving the sea at any hour of the night between 8 p.m. and 3 a.m., the turtle makes its way fifteen or twenty metres up the shore and there places her spherical soft-shelled eggs in a deep nest from which the young hatch after 58–65 days according to the intensity of the sun. In every nest of embryos examined by P. E. P. Deraniyagala there were two eggs containing twins. This author has made a very careful study of the development of the embryo and has found that the characteristic smooth-skinned condition of the adult results from the thinning out of the infantile scales which are not directly responsible for the corselet platelets (*Spolia Zeylanica*, **17**, 73 ; 1932). Nothing is known of the later development and growth of this turtle, of which the adolescent stage is unknown and appears to be spent far from land. The newly hatched young invariably sickened and died on a diet of fish. The morphological changes of the embryonic stages suggest a closer approach to the larval stages of Amphibia than is shown by any other living reptile. Apart from this feature, several of the adult characters, such as the clawless limbs, smooth skin, crested tail, skull characters, general build of the pelvis, and the cartilaginous nature of the skeleton, are reminiscent of the Amphibia.

The Painted Lady Migrates

In June the mass-movements of the painted lady butterfly (*Vanessa cardui*) reach their height in Europe. At the same time the migrations assume a new character which shows that mid-summer is for the painted lady the vague boundary which divides spring habits from autumn habits. Up to mid-summer, according to Dr. C. B. Williams, there is a prevailing tendency for the insect to move to the north and west, 94 flights in these directions have been recorded as against 59 in a southerly and easterly direction. In June, flights towards the south and east become more common and then predominate in July and August ; but although there is evidence of a definite movement northwards, there is no sound evidence of return migrations in autumn. The painted lady occurs in every continent of the world, yet their place of origin is still a little doubtful. In Europe the species does not survive the winter in numbers such as would give rise to large movements, and on account of the appearance of swarms entering Egypt and Algeria from the south, Dr. Williams surmises that the centre of dispersal lies somewhere south of the Sahara desert. His view is supported by the evidence of Skertchly, who in March 1869 saw emerging from their pupæ in grass in the Sudan, a cloud of painted ladies which was certainly more than a mile long and a quarter of a mile in breadth. The speed of migratory flight in this species appears to vary between 11 and 15 miles per hour whether with or against the wind, and a summation of the records suggests that there is probably no relationship between the direction of flight and the direction of the wind at the time.

American Pronghorn increasing in Numbers

In May or early in June the fawns of one of the oddest of horned ungulates are born, generally two at a birth, sometimes three. Although it resembles an antelope in appearance, the pronghorn (*Antilocapra americana*) is not closely related to the true antelopes of the Old World, and it is the only hollow-horned creature which sheds its horns every year. When white men first invaded the plains of western America, the pronghorn was more numerous than the bison ; but the spread of agriculture and grazing, and the gun, brought it a generation ago nearer to extinction than even that species. A campaign for the protection of the pronghorn has been most effective. A census just concluded by the New York Zoological Society gives the numbers (according to Science Service, Washington, D.C.) as approximately 68,000 in the United States and 2,400 in Canada ; whereas ten years ago, when the U.S. Biological Survey made a similar count, the numbers were 27,000 in the United States, and 1,327 in Canada.

Resistance of Turnips to Finger and Toe Disease

This is the turnip-sowing season in the north of England and in Scotland. In this connexion the experiments recently described by Prof. J. Hendrick of Aberdeen (*Trans. Highland and Agric. Soc. Scotland*, 1932, p. 52) with a variety of yellow turnip that is highly resistant to the 'finger-and-toe' organism, *Plasmodiophora brassicæ*, are of interest. For several seasons the Bruce, as the variety is now called, has produced good crops of usable quality on the well-known continuous turnip plots at Craibstone. Ordinary varieties of turnips are quite worthless on this heavily infected land. The control of finger and toe by liming is well understood, and represents one of the classic cases of the combatting of plant disease by modification of the soil reaction. Nevertheless, cropping with oats, potatoes and grass can proceed quite successfully on 'finger and toe land' and it may not be feasible or even desirable in all cases to undertake liming on such a scale as would cure the disease. A resistant variety offers a simple way out of the difficulty, and if the resistance of the Bruce is maintained, the variety should be a real contribution to the farming of acid soils in the turnip-growing districts.

Societies and Academies

London

Physical Society, May 5. N. R. Campbell: The measurement of visual sensations. The paper is a criticism of Dr. L. F. Richardson's proposed method of measuring sensations by 'mental estimates'. In the absence of agreed principles the discussion is conducted in the light of an analogy with thermometry. It is argued that if Dr. Richardson's facts and his implied propositions are true, indirect measurement by means of his *S* must be preferable to direct measurement by *R*. Arguments based upon the fact that this method of measurements leads to a numerical law between *R* and *S* would be valid only if the law is true and not empirical. If the method measures anything, that something is almost certainly not a sensation. Dr. Richardson's method indicates the theoretical possibility of a method of measurement based upon ordering differences of increasing degree; but there is no evidence that the method is ever practically possible. V. H. Stott: The measurement of the viscosity of a molten metal by means of an oscillating disc. It has been found necessary to calibrate the apparatus on molten metals having viscosities and densities not too different from those of the metals to be investigated. The viscosity of tin at different temperatures has been determined by Sauerwald and Topler by the capillary tube method, and the present experiments have lengthened the range of temperature for which the viscosity of tin may be regarded as fairly well established. Discontinuity in the (viscosity, temperature) curve of molten tin at temperatures near its freezing point is very improbable, and certainly does not occur at temperatures more than 6° C. above that point.

Dublin

Royal Dublin Society, Feb. 28. J. Carroll: Study of the potato eelworm (*Heterodera schachtii*) in the Irish Free State. The investigations include a study of the relationship between the parasite and the hydrogen ion concentration of the soil, and also a study of the relationship between the intensity of potato sickness symptoms and the number of eelworm cysts present in the soil. The experiments which were carried out, although of a limited nature, demonstrated satisfactorily that *Heterodera schachtii* can of itself give rise to severe symptoms of potato sickness, and that there is a positive relationship between the intensity of potato sickness and the number of cysts present. The paper also includes references to experiments on soil treatment and refers to other strains of the parasite which have been found in Ireland. H. H. Poole and W. R. G. Atkins: Some experiments on the suitability of photocells of the dry rectifier type for the measurement of daylight. Tests on these cells in intense illuminations show that the current illumination curves are rarely linear, their forms depending greatly on the resistance of the galvanometer employed. Temperature effects are important with some cells, and should be minimised by avoiding excessive exposure to strong light except for brief periods. Low resistance galvanometers are preferable as giving curves more nearly linear and less subject to temperature effects. A number of different cells were tested for their spectrum sensitivities, which were widely different according to the type of cell. The Bergmann cell is sensitive throughout the whole of the visible spectrum, its maximum being in the orange red. The permanence of this cell has not so far been tested, but all other cells tested have shown a fall of sensitivity with time and exposure. The cells appear to be well suited for rapid comparative measurements of daylight where great accuracy is not required.

Paris

Academy of Sciences, April 24 (*C.R.*, 196, 1177–1252). The president announced the death of R. de Forcrand de Coiselet, *Correspondant* for the Section of Chemistry. L. Cayeux: The rôle of the Trilobites in the genesis of the Palæozoic deposits of calcium phosphate. From the author's discussion it would appear that no important contribution of phosphate to Palæozoic strata can be attributed to Crustacea, especially Trilobites. Ch. Maurain: The interval of time between solar phenomena and terrestrial magnetic disturbances. Historical summary of published work on this subject. J. Costantin: Variations in the virulence of degenerescence in the potato. Discussion of the causes of resistance to disease. It is shown that the weight of crop per plant is a valuable criterion for determining the resistance to disease. M. Gignoux and L. Moret: The Briançonnais zone and the roots of the Savoy pre-alpine sheets. Mlle. Margherita Piazzolla-Beloch: A remarkable family of plane topological curves. Mlle. Marie Charpentier: Closed curves and their first ends. N. Botea: Holomorph functions. W. Stepanoff and A. Tychonoff: The spaces of nearly periodic functions. L. Pontrjagin: Nearly periodic functions and *Analysis situs*. Jacques Devisme: Two questions relating to the equation of P. Humbert. Antoine Appert: The rôle of the second condition of F. Riesz in abstract spaces and certain properties of connexion. Giovanni Lampariello: The analytical nature of the solutions of canonical equations integrable by quadratures. Robert L'Hermite: An indefinite plane piece submitted to the action of massic forces in the plane and the application to the calculation of rectangular drums supporting interior and exterior forces. J. Ellsworth: Remarks on the double system *RZ* Cassiopeiæ with eclipses. From an analysis of the known data the author concludes that contrary to the opinion of Hellerich, the photometric and spectroscopic data are not irreconcilable. J. J. Trillat and L. Leprince-Ringuet: Studies of the molecular phenomena at the surface of separation of oil and water. Applications to the control of oils. Changes in the surface tension at the oil water surface have been studied by Lecomte de Noüy's method, with special reference to the effects of traces of impurities in the oil. Proportions of impurities so small as 1/100,000 can be detected in this way. Jean Cayrel: A new detector. Studies in metal-crystal rectification. P. Lainé: The magnetic double refraction of liquid oxygen. The magnetic double refraction of liquid oxygen was found to be – 1·96 times that of nitrobenzene, slightly greater than the value found by Zernike (– 1·85). The dispersion was measured for three wave-lengths. Pierre Dubouloz: The yield of fluorescence of sodium salicylate. Studies of a potassium photoelectric cell coated with sodium salicylate. Applied to the photometry of the ultraviolet, it gives a convenient means of obtaining a very slightly selective receiver the sensibility curve of which is independent of the cell and its preparation. J. P. Mathieu: The alkaline tartaric solutions of chromium. Gaston Charlot: The catalytic oxidation of organic compounds in the form of vapour. P. Mondain-Monval and Roger Wellard: The direct oxidation of acetylene by air. Acetylene reacts with air at temperatures well below the polymerisation temperature, with production of peroxides. The peroxide is regarded as producing the spontaneous inflammation of detonating mixtures. A. E. Favorsky and J. N. Nazarow: The question of the existence of metal ketyls in the fatty series. André Meyer and Marcel Tuot: The dehydration of some tertiary alcohols by anhydrous copper sulphate. Anhydrous copper sulphate possesses the advantage over other dehydrating agents that, while giving good yields of pure ethylene derivatives, no isomerisation is produced. Raymond Hocart: The orientation of arsenolite and of senarmontite by mica. These minerals, sublimed on to a thin plate of mica obtained by cleavage, are oriented by the mica. H. Lagotala: The continental formation subjacent to the limestones of Niari (French Congo). The author regards the conglomerate formations studied as a continental formation of glacial origin, partially fluvio-glacial. N. Menchikoff: New data on the geology of the western Sahara. André Eichhorn: The supposed existence of centrosomes and of asters in the higher plants. The observations of Feng on *Lonicera* are not confirmed and another interpretation is given to his results. Vladesco: The development of the octants in the embryo of the leptosporangiate ferns. R. Quetel: The variations of the proportion of nitrogen in the lilac in the course of forcing. Study of the effects of exposure to ether vapour followed by placing in a moist, warm atmosphere. J. Verne and C. Sannié: Study of the toxic action of cations on fibroblasts cultivated *in vitro*. P. Ponthus: The action of an ultra-violet radiation on aqueous solutions of gelatine. Modifications of some physico-chemical characters. Probable photolysis. F. Rathery, Mme. Andrée Plantefol and Lucien Plantefol: The reactions of the respiratory exchanges resulting from the ingestion of glucose and of insulin in diabetics.

Rome

Royal National Academy of the Lincei, Jan. 8. F. Severi: The compatibility of systems of algebraic and analytical equations. C. Carathéodory: Generalisation of a theorem of Euler on brachistochrone movement. E. Almansi: Deformations of elastic plates (3). P. Aloisi: An andalusite twin. The crystal here described was found on Mount Perone (Elba) and represents the only case of twinning in andalusite. The twinning plane has, however, the simple symbol {101}, which is one of the few known forms of frequent occurrence in andalusite, and the various optico-crystallographic elements are arranged regularly in the positions proper to a twin on {101}. C. Agostinelli: Concurrent directions in a variety V_n. Study of the notion of concurrent directions, introduced by Myller (1928), by vectorial methods furnishes the conditions of concurrence in a very simple form and allows of the deduction of various noteworthy geometrical properties not previously recorded. S. Amante: Reduction of a special class of matrices to canonical form (1). L. Campedelli: Certain invariant series of groups of points on a surface. Ruy Luis Gomes: Linear operators: limited matrices. E. Gugino: Transport by parallelism along a closed circuit in a Weyl space. M. Kourensky: Integration of the equations to the partial derivatives of the second order with two functions of two independent variables (5). Systems containing two (or one) derivatives of the second order. S. Minetti: A general theorem on the succession of functions converging towards a holomorphous function. Maria Pastori: Tensorial aggregates generated by absolute Pascal-Vitali systems: relation to the derived aggregates. Emma Senigaglia: Complement of a theorem of A. Hurwitz on the basis of the modulus of the algebraic forms passing through a normal rational variety. D. Bonvicini: The second variation of the elastic potential in isotropic solids. An expression, sufficiently approximate for investigating the stability of the equilibrium, is derived for this variation. G. Lampariello: The quadrature which effects the integration of canonical systems with one degree of freedom. L. Sona: Forced viscous rotations. A. Weinstein: Wakes caused by circular arcs. F. Zagar: Increase in the mass of a planet by cosmic dust. (2) General case. A. Quilico and A. di Capua: Aspergillin, the pigment of the spores of *Aspergillus niger* (1). Of various media tried, molasses–agar gave rise to most abundant fructification of the mould. The Pollacci strain gave spores containing more than 24 per cent of aspergillin, whereas with a strain isolated from Abruzzian cheese the content did not exceed 15·6 per cent. Yields of aspergillin of 0·24–0·34 gm. and 0·10–0·22 gm. per square decimetre of medium surface were obtained; these may be increased considerably by removing the mycelium as well as the spores. R. Gigante: Preliminary investigations on a non-parasitic alteration of the olive. During last season the olives of Latium frequently developed slightly depressed greenish-brown spots of diameter 1–6 mm., which afterwards darkened. These were not the result of photolytic processes, deficient transpiration, or insect punctures, but appear to have been caused either by insect secretions or by fungicides having a molasses basis.

Vienna

Academy of Sciences, Jan. 27. Herbert Schober: The spectra of rhenium (4). Arc spectrum in the ultra-violet region on copper electrodes between 2400 and 4000 A. In the ultra-violet, more than 1800 lines have been identified in this spectrum, so that the total emission of rhenium in the copper arc between 8000 and 2400 A. shows about 3000 lines. The measurements agree well with those made simultaneously by Meggers at the American Bureau of Standards. Herbert Haberlandt: Luminescence investigations with fluorites (2). The occurrence, at Alland in Lower Austria, of a fluorite with a natural red photo-luminescence, is recorded. In general, the luminescence of fluorites is intimately connected with the paragenetic relations. Thus, in one case, it must be ascribed to the rare earths present and in another to bituminous impurities. Ludwig Lämmermayr: Comparative studies on the plants of eastern Styrian basalts and basaltic tufas (3). Ernst Nowack: The geological relationships of the region between Eregli and Bolu (Northern Anatolia). Gustav Götzinger and Helmut Becker: Stratigraphy of Wienerwald-Flysch east of Traisen.

Feb. 2. Guido Machek: Action of gaseous cyanogen on phenols and naphthols. (2) Dicyanogen and trihydroxybenzenes. (3) Dicyanogen and certain naphthols. The cyanisation of pyrogallol, β-naphthol, 2 : 3- and 2 : 7-dihydroxynaphthalenes proceeds with formation of molecular compounds. With phenol and hydroxyquinol, no individual products could be obtained, and phloroglucinol, α-naphthol, 1 : 3- and 1 : 4-dihydroxynaphthalenes did not react with cyanogen. **HANS PETTERSSON** and **JOSEF SCHINTLMEISTER**: Atomic fragments of short range from heavy elements. A new method of procedure is applied to the heavy noble gases, etc. **GERHARD KIRSCH** and **ROBERT TRATTNER**: Atomic disintegration with emission of neutrons. Of a number of elements subjected to irradiation with polonium α-particles, boron alone gives a number of neutrons comparable with, although smaller than, that yielded by beryllium. When tested by the Wilson method, the elements Li, C, N, Mg, Al, S, Fe, Cu, Zn, Pd, Ag, Sn, W, Pt, Au and Pb give definite but small effects, which are about 1 per cent of that obtained with beryllium. Molybdenum and nickel give effects of a lower order of magnitude and possibly emit no neutrons. With platinum and palladium, the effect has been confirmed in other ways (Geiger counter and photography) by measurement of the secondary absorption. **LUDWIG SELTENHAMMER**: Stability of the frame-rod arranged with parallel edges and compressed centrally. **KARL FRITSCH**: Observations on flower-visiting insects in Styria, 1913. Pollination of *Draba verna* L. is effected mostly by small species of the genus *Halictus*. With *Prunus*, the size of the pollinating insect conforms to that of the flowers; thus *Prunus spinosus* L. is visited more especially by small aphids, such as *Halictus* and *Andrena* species, and *P. avium* L. often by *Bombus* species. The names of various insects, not previously observed as pollinating insects in Styria, are given.

Forthcoming Events

Monday, June 12

VICTORIA INSTITUTE, at 4.30.—Sir Ambrose Fleming: "Free Will versus Determinism" (Presidential Address).

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—T. H. Harrisson: "The Oxford University Exploration Club's Expedition to Sarawak".

Thursday, June 15

ROYAL SOCIETY. Discussion on "The Experimental Production of Malignant Tumours" to be opened by Dr. J. A. Murray.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 8.15.—Annual General Meeting. Lieut.-Col. H. W. Aston (Director of School of Tropical Medicine and Hygiene, Calcutta): "Carriers of *Entamœba histolytica* and their Treatment".

Nationalism and Academic Freedom

GERMANY, responding to the call of a patriotic emotion—as she has more than once before, but never with such abandon—would appear to have handed herself over body and soul to Herr Hitler. Acting on a given view of history and a prescribed theory of racial and national regeneration, she seeks to purge herself of elements felt to be inimical or to stand in the way of the realisation of his ideal. A new communism, imposed by force, but accepted widely if not yet universally, with an enthusiasm which appears to have crossed the bounds of fanaticism, bids fair to reduce the whole of Germany as nearly as is humanly possible to one common denominator and to block every angle of vision but one in her political and intellectual kingdoms alike.

Both historian and anthropologist may look askance at the Hitlerian view of racial history and psychology as suspect in origin. They may dismiss with a smile the 'Aryan' claim to exclusive rights in the swastika. It is not the first time that ethnological facts have been 'edited' to bolster political aspiration or flatter national vanity ; nor will it be the last. If, in electing to remould herself as an 'organised State', Germany has chosen to rely on the hypnotic effect of a pseudo-scientific theory now exploded—an instrument which may break in her hand—that is her affair and concerns no one but herself. In expelling from public life those who, on racial or political grounds, are regarded as beyond the pale, Germany, by her own act, deprives herself of the services of some of her most eminent intellectuals. These are men prominent in the arts and sciences, in public life, in the professions and in education, who have raised and maintained her in the foremost ranks of intellectual achievement among the nations. This may well seem a blunder, at which the whole civilised world stands aghast, a misreading of history and a fatal misinterpretation of the conditions of progress in a modern society, in which, in these days of fierce competition, every resource of science is pressed into the service of social and commercial advancement. Yet even such action as this, although it has its international aspect, as a domestic matter, it is held, does not concern the outside world. But in forbidding men of German nationality, who have served their country loyally in peace and war, to exercise their talents, and in depriving them of the means of livelihood, Germany has been guilty, in the eyes of the world, of an act of grave injustice, which has made intellectual companionship with her difficult.

It is fully in accord with the tradition of religious and political liberty in Great Britain that the first attempt on a comprehensive scale to organise a scheme of assistance for the scholars, men of science and university teachers who have been forced to relinquish their posts in Germany should have been made by their British colleagues. It was never in doubt that, for men of the first rank and of international fame, room would be found without delay in the universities of other countries. This belief has been justified by the event. It did not seem likely that it would be possible in the normal course for academic institutions outside Germany, however great their goodwill, to absorb more than a few of those of less outstanding repute, and that too, perhaps only after some considerable delay. The difficulties are enormously increased by financial conditions, collective and individual, in the academic institutions of all countries alike. In teaching and research, competition for appointments at the moment is intense; and it would be neither fair nor practicable for a 'most-favoured nation clause' to be extended to displaced German teachers and research workers; while the requirements of the normal development of university work are such that it is unlikely that many universities would feel justified in making special provision for them. As the result of inquiry, it would appear that this is only too just an estimate of the position. Appointments will be available for only a small fraction of those in need.

It is in view of considerations such as these that, as already noted in NATURE (June 3, p. 793), the Academic Assistance Council has been organised. A provisional council has been formed which has issued a statement of the aims and methods to be followed, should the necessary support be received. The Academic Assistance Council will act in a double capacity. In the first place it will serve as a centre of information and as an organisation which will put the teachers concerned into touch with the institutions where they can work; and secondly, it will seek to raise a fund to be used primarily, though not exclusively, in providing maintenance for displaced teachers and finding them a chance of work in universities and scientific institutions.

There are several points arising out of this appeal which call for comment. Of these the most considerable is the effect of German action on science at large. While Germany may claim as a matter of domestic concern to lay down such regulations for appointments in and admissions to her academic institutions as she may deem fit, apart from all questions of justice it is a matter of concern to the whole scientific world that a number of workers, now considerable, be they Jews, or members of any religious or political group whatsoever, are deprived of the opportunities they have hitherto employed in adding to the sum total of scientific knowledge—researches by which ultimately the whole world has benefited, irrespective of nationality. It requires no special pleading to show that while Germany persists in her present attitude towards Jews and other men of science within her jurisdiction who do not conform to type, it is of advantage to the whole scientific world and an international obligation to ensure that everything possible is done to secure the continued benefit to science of the services of these displaced workers. The international appeal of the situation and the need for international action has not been overlooked by the provisional council. It is in relation, not merely with British universities, but also with bodies formed for a purpose similar to its own in other countries.

Unfortunately, the situation in Germany is not unique; and the Council proposes to utilise any funds entrusted to it for the purpose of assisting university teachers and scientific workers of whatever country who on grounds of religion, political opinion or race are unable to carry on their work in their own country. There is no doubt, however, that for the moment the situation in Germany is the most critical. The appeal records the names of a long list of teachers who have been dismissed, have resigned on account of student action, or are on enforced leave. Yet long as it is, it is confined to professors, extraordinary professors and *Privatdozenten* in institutions of university rank, and is stated to be incomplete.

It should be no matter for surprise that, while the appeal has been received with much sympathy, it has aroused misgiving, in view of the financial situation and the difficulty of finding appointments for trained scientific men, many with high qualifications, from our own universities and places of higher education, while among school teachers the position is equally, if not more, grave. Obviously it would be far from politic, and indeed unfair to the displaced teachers and research workers, to offer them posts in a market which is already overstocked. The Academic

Assistance Council has shown itself fully alive to the situation. Its proposals will, it is understood, take the form that any funds raised should be devoted to the creation of special posts and lectureships *ad hoc*, and that these will be of limited duration, a term of years at the end of which it may be anticipated that a process of adjustment will have worked itself out.

The appeal of the provisional council, of which Sir William Beveridge and Prof. C. S. Gibson act as secretaries, has already received a substantial measure of support. Office accommodation has been placed at the disposal of the Council by the Royal Society, and the appeal carries the names, among others, of Sir Frederick Gowland Hopkins, president of the Royal Society and of the British Association, Lord Buckmaster, Lord Cecil of Chelwood, Lord Crawford and Balcarres, Sir William Bragg, Mr. H. A. L. Fisher, Sir George F. Hill, director of the British Museum, Sir Frederic Kenyon, Mr. J. M. Keynes, Lord Lytton, Dr. Allen Mawer, Dr. Gilbert Murray, Lord Eustace Percy, Sir William Pope, Lord Rutherford, Sir Josiah Stamp, Sir J. J. Thomson, Sir Michael Sadler, Sir Charles Sherrington, and Prof. G. Elliot Smith.

The Development of Indian Thought

(1) *A History of Indian Philosophy*. By Dr. Surendranath Dasgupta. Vol. 1. Second impression. Pp. xvi+528. 30*s*. net. Vol. 2. Pp. xi+620. 35*s*. net. (Cambridge: At the University Press, 1932.)

(2) *Outlines of Indian Philosophy*. By M. Hiriyanna. Pp. 419. (London: George Allen and Unwin, Ltd., 1932.) 16*s*. net.

A COMPARATIVE study of Eastern and Western thought cannot but widen the understanding of philosophy as a collective effort to apprehend the ultimate sources of knowledge and life. It would also suggest to thinkers of either tradition, new methods of approaching these fundamental problems. A great deal of pioneer work still has to be done in both directions, in order to facilitate the accessibility and interpretation of the existing texts. The West has already published a large amount of original writings, critical editions and historical studies of its leaders of thought; but the East has the technical disadvantage of having entered rather late in the field of practical scholarship. Prof. Dasgupta tells us, for example, how the publication of the second volume of his great "History of Indian Philosophy" was delayed, among other reasons, by the fact that he had to read numerous unpublished and unknown texts, and to decipher patiently the handwriting of old and moth-eaten manuscripts.

Indian philosophy is so rich and complex, that it is impossible to estimate its progress without the help of an expert guide who would initiate one into the technicalities and intricacies of a difficult but most inspiring subject. We owe therefore a debt of gratitude to Prof. Dasgupta and to Prof. Hiriyanna, for their historical and exegetical efforts. Though their aims are different, their works are fully equal to their respective purposes. While Prof. Hiriyanna aims at no more than giving a well-balanced general outline of Indian philosophy, Prof. Dasgupta intends to give a detailed exposition of Indian thought strictly on the basis of the original texts and commentaries. Yet, they both follow almost the same order in their exposition, though Prof. Dasgupta is more patient about details, and gives one additional chapter of great interest on the conceptions of the Indian medical schools. The extensive bibliography in Prof. Dasgupta's two volumes adds to their scientific value.

One must go back to the sacred Vedas for the early sources of Indian philosophy. The Vedic gods, with their cosmogonic implications, must have been the first objects of independent thinking. Behind them, however, the concept of Brahman came to acquire a great significance as the supreme principle of everything. Yet the monotheistic tendencies thus developed, never displaced the ritualistic inclinations of the early Hindus, who cultivated diligently their polytheistic sacrifices. On the other hand, the law of Karma, which identifies sacrifice with action, implies a most effective causally related universe; so that the natural virtues attributed to the sacrifices lessened gradually the importance of deities as the supreme masters of the world and our fate. The ultimate unity of the universe soon gave rise to the idea of a world-soul (Atman), the highest essence in man as well as in the universe, which was to take such a great importance in the Upanishads. So far, it may be observed, the development of the early Vedic philosophy has a striking parallel in that of Greek philosophy, in which the gods of Homer had ultimately to give way before the urgent rational quests for the ultimate nature of things and for order in the universe, culminating in the recognition of a νοῦς by Anaxagoras.

The parallel develops further when we pass from the Vedas to the Upanishads. Just as it was the case when the centre of interest was displaced by Socrates from the outside world to the self, so, with the Upanishads, the attention of the thinkers is decisively focused on the self, instead of being directed to the Creator outside. This is a considerable change, though the Upanishads or Vedantas are believed to be the last portion of the Vedas. The fundamental idea which runs through the early Upanishads is that, underlying the external world of change, there is an unchangeable reality which is identical with that underlying the essence of man. The quest after Atman, with its many variations and implications, becomes the main concern of the philosopher. The post-Vedic writers have thus a good deal to say about the world, causation, the evolution of the soul and transmigration, and the final state of transcendental bliss which should be that of the soul when at the end of its inexorable cycle, conditioned by the all-pervading law of Karma. In spite of their unity of endeavour, all the Indian schools do not see eye to eye the possible answers to these problems. One of the reasons of the diversity of opinions is that the sutras of the sacred Brahmanic texts are mostly unfinished sentences the meaning of which has to be guessed rather than obviously stated.

These complications increased with the growth of Buddhism and Jainism, both schools outside the pale of orthodox Brahmanism. Though it is said that Buddhism derived much of its inspiration from the oral Samkhya and Yoga traditions of the Vedas, there is no doubt that it introduced entirely new conceptions into Indian philosophy. By denying the substantial and eternal Atman, Buddhism could not teach the conscious transcendental bliss which was the final state admitted by the Vedas. As our experience never apprehends the essence of things, but only our own perceptions, consciousness is nothing but a group of bodily and psychical states which, at death, disintegrate and merge into an unconscious nirvana. The main concern of Buddhism was the answer to the four 'noble truths': What is sorrow ? What is the cause of sorrow ? What is cessation of sorrow ? What can lead to the cessation of sorrow ? The whole of Buddhist doctrine is the development of the answers to these questions. The denial of a permanent external world and of a permanent soul leads to a complete upsetting of the major tenets of the Brahmanists about the unity, causality and purpose of the world and of life. It is interesting to note, however, that Buddhism had to develop a certain logic for its dialectic purposes. Thus we find in the Sautrantika theory of inference, that the Buddhist knew actually the doctrine of distribution of terms, of conversion, and of the hypothetical syllogism, during the third century before our era.

Jainism, on the other hand, took the opposite view about the world, admitting the permanence of the substance under the changing accidents, and identifying being as the union of permanence and change. This relative pluralism, as opposed to the extreme absolutism of the Upanishads and the extreme pluralism of Buddhism, was further emphasised by the Jainist doctrine of the 'nayas' or points of view in a judgment, which held that no truth is absolute but only conditional, and that the test of knowledge is that it helps us to attain our purpose—a striking anticipation of pragmatism.

These cross-currents in Indian philosophy influenced considerably the age of the systematic doctrines, as may be gathered from the conflicting opinions about the world, causation, perception, inference, the origin of knowledge and the rules of right conduct, put forward by the Samkhya and Yoga schools, the materialist conceptions of Carvaka-darsana, the Nyaya-Vaisesika philosophy, the Purva-Mimansa teaching, and the various Vedanta schools, such as the Sankara, Advaita and Visistadvaita traditions. In spite of their differences, these systems are remarkable products of rational thinking. Fine distinctions on logical problems, ontological and psychological theories, and ethical experiences and rules of conduct, illustrate the amazing versatility of the Indian mind and the sensibility of the Hindus. Translated into occidental language, these distinctions would no doubt prove quite capable of enriching the vast syntheses of our great thinkers. The qualified indications contained in the two works under review are already by themselves an ample mine of material for immediate use.

Before closing our remarks on the development of Indian thought, we wish to direct attention to the learned chapter on the "Speculations in Medical Schools" in the second volume of Prof. Dasgupta's work. Medicine was the most important of all the physical sciences in ancient India; and its conceptions are closely connected with such doctrines as the Samkhya and Vaisesika physics and the ethical teaching of the Vedic tradition. The earliest texts on medicine, which formed the basis of later commentaries, are those of the Atharva-Veda, which may have been composed by Brahma himself. In them, one finds a mass of information about the organs of the body, embryology, symptoms and observations of diseases, the use of medicines and charms, and, of course, a store of prayers, imprecations and hymns for the cure of certain diseases. Observations about the head, the heart, the circulatory and nervous systems are very important too, in so far as they have been taken as the basis of rival medical and psychological theories, such as the Tantras and the Caraka and Susruta schools, which give the spinal column and the heart, respectively, as the fundamental organs. There are also detailed speculations about the elements of the world and the elements of the body which, at times, bear a striking resemblance to the Hippocratic teaching and to that of the medical school of Crotona.

In conclusion, we can do no better than quote Prof. Hiriyanna's estimate of Indian philosophy (p. 24):

> "The two elements common to all Indian thought, are the pursuit of liberation as the final ideal and the ascetic spirit of the discipline recommended for its attainment. They signify that philosophy as understood in India, is neither mere intellectualism nor mere moralism, but includes and transcends them both. They have been represented as the two wings that help the soul in its spiritual flight. The goal that is reached through their aid is characterized on the one hand by illumination which is intellectual conviction that has ripened into an immediate experience, and, on the other hand, by self-renunciation which is secure by reason of the discovery of the metaphysical ground for it. It is pre-eminently an attitude of peace which does not necessarily imply passivity. But the emphasis is on the attitude itself or on the inward experience that gives rise to it, rather than on the outward behaviour which is looked upon as its expression and therefore more or less secondary. The value of philosophic training lies as little in inducing a person to do what otherwise he would not have done, as in instructing him in what otherwise he would not have known; it consists essentially in making him what he was not before. Heaven, it has been remarked, is first a temperament, and then anything else."

THOMAS GREENWOOD.

Research on Vitamins

Medical Research Council. Special Report Series, No. 167: *Vitamins; a Survey of Present Knowledge.* Compiled by a Committee appointed jointly by the Lister Institute and Medical Research Council. Pp. 332 + 12 plates. (London: H.M. Stationery Office, 1932.) 6*s*. 6*d*.

THIS book is both the most comprehensive and the most official of all publications so far available on its subject. It is the most comprehensive because it surveys all work up to the end of 1931, thus beating Sherman and Smith's monograph and Dr. Ethel Browning's vast compendium by several months; it is the most official because it is the only work on the subject, apart from its own earlier editions, that has been produced under the auspices of a government department.

To describe it, however, as a new edition of the earlier volumes is somewhat misleading; the revisions have been so exhaustive and the rearrangement in certain cases so fundamental as to make it a new work altogether. It is interesting to learn from the foreword that it is not proposed to revise it again or to publish any further editions. The reasons for this decision can best be given in the words of the Medical Research Council, which itself is responsible for issuing the report.

> "It can hardly be contemplated that the rapid and accelerating growth of the subject can be conveniently followed further by fresh revisions of such a monograph as this. The labour entailed and the sacrifices of time made by research workers in successive revisions of such a monograph are not likely to be justifiable again. The Council have joined with the Reid Library of the Rowett Institute, Aberdeen, and the Imperial Agricultural Bureaux Council, in giving financial support to a new periodical journal, "Nutrition Abstracts and Reviews", of which the first number appeared in October last [1931]. The Council hope that this will provide for the future a regular means of bringing together and making more readily available the results of research work as they accumulate in the now widely distributed and often disconnected fields of work, medical, agricultural, dietetic, and commercial, in which the subject of nutrition is being so rapidly developed."

Both the decision, and the reasons given for it, are symptomatic of the present condition of vitamin research. Not only has the subject become a recognised branch of biochemistry with repercussions in the extreme directions of pure chemistry and of applied medicine, but it is also just now at a stage when so many growing researches are about to blossom that it would be almost impossible to lay adequate plans for similar publications in the future. Indeed, the history of vitamin research since this book was published, and still more since the date of the latest publications included in the survey, give ample evidence on the matter.

During 1932 pure crystalline vitamin D became a commercial commodity: further advances have been made in investigating the nature of crystalline vitamin B_1, and the purity of the most concentrated specimens is probably little short of 95 per cent: highly concentrated preparations of vitamin A have now been made (see Carr and Jewell, NATURE, January 21, 1933, p. 92) of probably the same degree of purity as crystalline B_1, but unfortunately not themselves crystalline: Reader and her colleagues (*Biochem. J.*, 26, 2035; 1932) have announced the preparation of what may prove to be crystalline vitamin B_4: the identification of vitamin C with ascorbic (hexuronic) acid is now accepted by nearly all workers in the field.

It is clear that, as these researches reach fruition, investigation of the structure of each particular vitamin will cease to be a biochemical problem and will pass into the hands of the pure chemist. As soon as a vitamin becomes a definite, recognisable, and determinable entity—in the sense that accurate chemical measurement constitutes a determination while biological assay only constitutes an estimation—the hands of the physiologist and clinician will be immensely strengthened in their attempts to work out its precise metabolic function.

How much has already been achieved in this direction, in spite of the difficulties invariably confronting those who work with substances that can only be assayed biologically, is admirably told in this indispensable summary. Although in one or two places it may be possible to detect the individual views of well-known authorities, the objectivity of the volume as a whole is beyond reproach. Considering the fact that the actual text only occupies some 270 pages, its comprehensiveness is quite astonishing. It is, indeed, amusing to notice how often, on turning to the index to find a reference to some aspect of the problem that one thinks has been overlooked, one does indeed find a reference, or more than one, to that very aspect.

On certain matters the authors of particular sections have expressed themselves with refreshing definiteness. On page 69 we find it said that "There is no reason to believe that any of the toxic actions ascribed to cod-liver oil are due to its vitamin content". On page 122 it is stated that "The rat . . . requires for satisfactory nutrition four vitamins of this group, B_1, B_2, B_4, and factor Y: the pigeon at least three vitamins, B_1, B_3, and B_5". This is, incidentally, not a view that would be accepted by all those who have worked with the B complex; it is certainly held by some that the pigeon needs vitamin B_2. On page 227 it is interesting to read "About 500–1,000 c.c. (1–2 pints) of raw cow's milk provides enough or nearly enough of the vitamins A and C and of the B-vitamins of the yeast complex, but not enough of vitamin D. Cow's milk, however, is so variable in composition that this statement may need qualifying, and does not provide more than a slender basis for calculation".

It is perhaps legitimate to observe that cow's milk may here be suffering rather more from the amount of attention that has been given to it than from any fluctuation in the vitamin content of milk, as distinct from other foods. Probably far more samples of cow's milk have been assayed for vitamin content than any other single food-stuff, and it is not surprising to find very different results reported by different workers. It is at least conceivable that any other food substance that had been examined so often and in so many different parts of the world would show similar irregularities. The practice of arguing from the study of a particular sample of a particular substance that all other samples of the substance, wherever produced and under whatever conditions, will contain much the same amount of the vitamin as the sample examined, is all too prevalent in vitamin literature, and has led to generalisations as glib as they are fundamentally unsound and unconvincing. Nevertheless, it is gratifying to note the immense amount of information that is already available and only awaits co-ordination and extension to be made the basis of a really scientific consideration of world dietary problems.

The compilers of this report, owing perhaps to a modesty that we hope is characteristic of scientific workers in Great Britain, have a freedom from scientific chauvinism which is both rare and gratifying. The specialist in vitamin work has been irritated, at least as often as the specialist in other fields, by the production of books purporting to be objective studies of a subject, but found on inspection to be little more than a summary of their authors' own work and views. He has also been exasperated by books issued under titles promising comprehensive surveys of a whole subject, only to find that scientific workers of the author's own nationality must have been seriously under-rated by all the rest of the world, if the author's assessment of their work is to be regarded as correct. This volume is devoid of such faults. Naturally, American and British workers, who have indeed been first in many vitamin fields, receive most attention, but that this fact is not due to accidents of birth and language, is fully attested by the 26 pages of references at the end of the book. If English and American names, indeed, predominate here and in the text, German, Scandinavian and French names are to be found in plenty, supplemented occasionally by those of workers in many other countries.

It is, indeed, doubtful whether the book could have been made more comprehensive or freer from any suspicion of personal views and prejudices had it been produced by, say, the Health Organisation of the League of Nations. As it is, it carries just sufficient impress of the personalities compiling it to make it something very much more than an occasional reference book. For all those in any way interested in the development of the subject, it is a volume that not only must be read but will also be found to be very readable.

A. L. BACHARACH.

Membrane Equilibria

The Donnan Equilibria: and their Application to Chemical, Physiological and Technical Processes. By Dr. T. R. Bolam. (Monographs on Modern Chemistry.) Pp. vii+154. (London: G. Bell and Sons, Ltd., 1932.) 9*s.* net.

THE conditions of equilibrium in a system in which one component is unable to escape from the phase in which it is found, but is able to combine with another substance which can escape from the phase, were worked out by Willard Gibbs. The importance of equilibria of this type was not realised, however, until Donnan and Harris in 1911 described the behaviour of common salt when added to a system in which an aqueous solution of Congo red (the sodium salt of a complex sulphonic acid) was separated from pure water by a membrane through which the anion of the colloidal electrolyte could not pass. The concentration of sodium chloride was found to be greater in the solution which did not contain the colloidal electrolyte. Finally, a condition of equilibrium was reached when the product of the concentration of the sodium and chlorine ions, $[Na^+] \times [Cl^-]$, was the same on both sides of the membrane.

This type of 'membrane equilibrium' is of special importance in physiology, and was in fact described before the London Physiological Society in December, 1910. It is not necessary, however, that a membrane should be present, since similar conditions of equilibrium prevail whenever one ionic component of a pair of salts is prevented from diffusing freely. This non-diffusibility may be realised, for example, in a jelly, or it may be caused by adsorption at a surface.

The present volume describes, in a series of four chapters, the theory of the equilibrium, and its applications in chemistry, physical chemistry and biology. In addition to name and subject indexes, it contains a bibliography containing 143 entries. These include a few references to standard works on thermodynamics, etc., but are mainly citations from physico-chemical and physiological journals in which illustrations are given of the influence of the tethered ion on equilibrium in living and non-living systems.

Short Reviews

The Calendar and its Reform. By F. A. Black. Pp. viii+80+3 plates. (London and Edinburgh: Gall and Inglis, 1932.) 2*s.* 6*d.* net.

THIS book describes in detail the various stages which led to the adoption of our present calendar; it begins with the half legendary calendars of Romulus and Numa Pompilius, goes on to the reform of Julius Cæsar, and the alterations (for the worse) introduced by Augustus. There is a chapter on the origin of the names of the months and weekdays, followed by one on the introduction of the use of the Christian era for reckoning years. Then we have the Gregorian reform, and a discussion of the small errors that it involves. Incidentally, it is mentioned that the beginning of the financial year on April 5 is a relic of old style, when the year began on March 25; that day became April 5 after the change. The author is under a misconception in asserting on p. 37 that the slight shortening of the year since the days of Hipparchus depends on the observations made by the latter; it depends on modern observations and calculations.

Mr. Black then comes to the vexed question of calendar reform; he wisely notes that the proposal of many calendar reformers to put five days in four years outside the regular sequence of weekdays excites such strong opposition that there is little chance of carrying it; in fact it blocks the way of reform. The author proposes as an alternative that ordinary years should have exactly 52 weeks and leap years exactly 53 weeks. A simple rule for the fixing of the leap years is given; there are in general two of them in eleven years, but the number is adjusted to give exactly the same number of days in 400 years as in the Gregorian calendar. Under this system the weekdays would recur every year on the same days of the month, which is the principal aim of the reformers; but there would be no tampering with the sequence of weekdays. A full calendar for the next 400 years is given under the proposed system; the greatest divergence from the present calendar is one week.

Suggestions are also given as to the lengths of the months; the author would make them 35, 28, 28 days in each quarter: in leap year one quarter would be 35, 28, 35 days. The lengths of the months are, however, subsidiary to his main proposal.

The Analysis of Fuel, Gas, Water and Lubricants. By Prof. S. W. Parr. (International Chemical Series.) Fourth edition. Pp. xv+371. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1932.) 18*s*. net.

THE book is divided into two parts, the former covering a wide range of subjects, with coal as their common basis, the latter dealing with laboratory methods. Such a work as compiled by the late Prof. Parr should have a wide public, if only some means could be devised of gaining its interest. The individual chapters are based on lectures and are most readable, since their writer had the gift of simple and direct expression. An attractive feature for the reader is the emphasis laid on the historical side of the subject, so far as America is concerned: copies of Joliet's map of the Mississippi valley made in 1674 and of La Salle's colony on the Illinois in 1684 show the beginnings of an industry which from a production in 1830 of 320,000 tons, representing a little more than one-fiftieth of a ton per capita, advanced to a total of 550,000,000 tons in 1930, almost 5 tons per head.

The scope of this book is best indicated by the chapter headings; they include the distribution and production of coal, the development of research and the science of calorimetry from the days of Count Rumford onward, in which the work of Parr has played a useful part. Then follow sections on the constitution and classification of coal, the absorption of oxygen, and ignition temperature in relation to the storage of coal. The question of impurities and coal contracts receives attention, also the smoke evil. Combustion and carbonisation are discussed, likewise coke and gas. Sections are devoted to wood, liquid fuels, lubricants and boiler waters.

The book is well illustrated and clearly printed. It is primarily intended for American readers, who are favoured in having available such an adequate summary of the whole subject of fuel.

Bell's Popular Science Series. *Old Trades and New Knowledge: Six Lectures delivered at the Royal Institution.* By Sir William Bragg. Pp. xii+266+42 plates. *The World of Sound: Six Lectures delivered at the Royal Institution.* By Sir William Bragg. Pp. viii+196. *Living Machinery: Six Lectures delivered at the Royal Institution.* By Prof. A. V. Hill. Pp. xiv+256+24 plates. (London: G. Bell and Sons, Ltd., 1933.) 4*s*. 6*d*. net each.

REFERENCE was made in our issue of December 10, 1932 (p. 878) to the first four volumes in this attractive series. Three more have now appeared, all of them emanating from the Royal Institution. Sir William Bragg is a master of the art of popularisation and his lectures on the applications of physics in commercial processes and on sound are models of their kind. Prof. A. V. Hill's Christmas lectures on the machinery of the human body will probably be remembered for the experimental illustrations he gave, using his own children as subjects—to their delight and to the concern of the uninitiated. Messrs. Bell are to be congratulated on the production in cheaper form of these fascinating courses of lectures.

Wave Mechanics: Elementary Theory. By Prof. J. Frenkel. Pp. viii+278. (The International Series of Monographs on Physics.) (Oxford: Clarendon Press; London: Oxford University Press, 1932.) 20*s*. net.

ALTHOUGH complete in itself, this is intended to be the first of three volumes and gives a general survey of the whole subject of wave mechanics. The word 'elementary' in the title should not mislead the reader. The book is not a mere description or attempt to evade mathematics, but is introductory to the more detailed volumes to follow. First comes the derivation of the photon from Einstein's relativity mechanics and its extension to the wave packets of Schrödinger and the uncertainty relation of Heisenberg. The wave mechanics of a particle, system of particles, statistical mechanics and applications of quantum statistics to the electron theory of metals follow.

Photocells and their Application. By Dr. V. K. Zworykin and Dr. E. D. Wilson. Second edition. Pp. xxv+331. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1932.) 18*s*. 6*d*. net.

THE second edition is a considerable enlargement of the first. It constitutes a valuable account of photoelectric cells of all kinds, but more particularly of the photo-emissive type. The history of the photoelectric effect is given and is followed by an account of the production of alkali metal films and composite films and of the various processes of manufacture of cells. Circuits suitable for detection are described for all types of cells, photoconductive and photovoltaic as well as emissive, and sufficient theory is given to make the account of value. Applications to photometry, facsimile transmission and television are also included.

Scientific Professionalism

IN contrast to the trade union movement, which has received much attention both in its historical aspects and in relation to the social and economic problems it presents, professional associations have been almost entirely neglected. There has been no study of the historical development of professional association or of the social, economic and ethical problems involved. In view of the growing importance of the expert in public life, the position and influence of professional associations possess a wide interest.

We may perhaps begin with the medical profession. Its present organisation is based upon the Medical Act of 1858, which created the General Council of Medical Education and Registration of the United Kingdom, usually known as the General Medical Council. This Council, which is subject to the Privy Council, has two main duties, to ensure that the unfit do not get on to the register and to expunge the unworthy from it. While the General Medical Council has no option but to register those who produce a licence from a duly accredited authority and tender the prescribed fee, it is empowered to erase a name from the register in certain circumstances; although neither teaching nor examining, it can enforce such minimum standards of education and examination as it pleases. The topics which the General Medical Council is competent to discuss are, however, limited, and exclude, for example, all questions relating to remuneration. These questions, particularly the pay and status of medical officers in the Services and under local authorities, and of practitioners under the National Health Insurance scheme, are main fields of activity of the British Medical Association, though it would be difficult to overestimate the contribution of the latter also to medical science and practice.

The British Medical Association was founded at Worcester in 1832, although it did not assume its present title until 1856. Its membership embraces 35,000 of the 55,000 names on the medical register and probably includes three-quarters of the medical men in practice in Great Britain. Its constitution in its present form dates from 1902 and the effective control of the Association lies with the Representative Body, consisting chiefly of delegates elected by the divisions. The Representative Body is the parliament of the Association and debates at its meetings are keen. Persistent skilful leadership has played a large part in raising the status and remuneration of doctors and although there is little evidence regarding the average income of the general practitioner, it is significant that the Association is able to obtain a minimum commencing salary of £600 a year for a whole-time medical officer of the lowest grade. At the arbitration inquiry in 1926 it was stated that £1,200 might be the average income from a successful practice "not at the top". Evidence was given before the Royal Commission on the Civil Service in 1930 that a fully employed panel doctor in a populous area, using half his time for panel and half for private practice, could make £1,400 net per annum. The salaries offered to medical men are considerably higher than those for dentists or for veterinary surgeons.

The position of the veterinary surgeons presents analogies with the position of the medical profession but is weaker mainly through the neglect of veterinary science in Great Britain. The Veterinary Surgeons Act of 1881 laid upon the Royal College of Veterinary Surgeons the duty of keeping a register but, unlike the General Medical Council, also of examining the students of recognised veterinary colleges. It possesses disciplinary powers and its members have certain privileges similar to those granted to doctors. The numerical weakness of the profession—the register contains 3,473 names for the British Isles—and prevailing indifference to veterinary science largely account for the comparative impotence of the National Veterinary Medical Association.

The engineering profession offers strong contrasts to the conditions of the medical profession, particularly in the absence of any legal register and in the number of specialist organisations which have developed as the range of engineering grows. The parent society is the Institution of Civil Engineers, founded in 1818, the activities of which for the first fifty years were confined to study. For long enough membership, however, did not imply scientific training and only in 1897 did the Institution establish its own examinations. There are grades of membership, corresponding to different degrees of attainment and experience. Associates must be more than twenty-five years of age and have passed either the examinations of the Institution or an approved examination and have undergone a specified period of practical training. Members must be more than thirty-three years of age and have been associates with five years' experience in a position of responsibility, or have had "suitable education and training as a civil engineer" and fifteen years employment in a position of responsibility and have acquired "a considerable degree of eminence in the profession". Rules governing the professional conduct of members were not formed until 1910 and their general purport is to ensure that the engineer's utmost skill shall be placed at the disposal of those who employ him, and that the method of remuneration shall not involve any conflict between his personal interests and those of the clients whom he advises.

Round the Institution of Civil Engineers have sprung up the Institution of Mechanical Engineers, the Institution of Naval Architects, and the Institution of Electrical Engineers, as well as other junior institutions such as the Institution of Mining Engineers, the Institution of Structural Engineers, the Institution of Automobile Engineers, the Institution of Gas Engineers and the Institution of Chemical Engineers. These are not rival associations though they are modelled on the parent society and the membership overlaps considerably. The civil and mechanical engineers have memberships of about 10,000, the 'electricals' about 11,500, the naval architects about 3,000 and the mining engineers 3,800. The number of qualified engineers in Great Britain is estimated at 26,659.

The professional organisation of chemists in Great Britain has been handicapped by the assumption of the title of "chemist" under the Pharmacy Act of 1868 by members of another vocation possessing one or more alternative titles. The growth of the profession is frequently referred to the formation of the Chemical Society in 1841, which, however, has remained a study society and never demanded scientific or practical qualifications of its members. The first steps at professional organisation were taken in consequence of the passing of the Sale of Food and Drugs Act in 1875, and led directly to the founding of the Institute of Chemistry in 1877. Although its interests were originally mainly limited to those of analytical and consulting chemists, since 1918 it has included a large number of those practising in industry. Its present membership of nearly 6,000 probably represents from one half to three quarters of the fully trained chemists in Great Britain.

The Institute of Chemistry has done much to raise the status of the public analyst, but it has been able to do relatively little to raise the status or remuneration of the chemist in general, and the prestige and value of its membership have not become such that all qualified to obtain it do in fact apply. More effective professional defensive work for chemists generally is being done by the British Association of Chemists, in spite of a much smaller membership—a little over 1,000—largely on account of the greater freedom permitted by its constitution and by its registration under the trade union acts. The Institute of Chemistry is an examining body but the fellowship and associateship can be obtained with partial or complete exemption from examination by those holding recognised degrees or diplomas with first or second class honours in chemistry. The British Association of Chemists also admits those with a sufficient general education and scientific training who have had at least seven years' practice in pure or applied chemistry. The estimated number of chemists is about 10,000 of whom not more than 350 are in private practice. Inquiries conducted by the Institute of Chemistry in 1930 indicated that 15 per cent of fellows at home were receiving between £1,000 and £1,500 and nearly 50 per cent between £500 and £1,000; of associates at home 25 per cent were receiving £500 to £1,000 and 62 per cent from £250 to £500. Members abroad were getting considerably higher salaries.

Reference has been made to the pharmacists, whose early history is closely related to that of the medical professions through the apothecaries and "chemists" and "druggists". The Pharmacy Act of 1868 prohibits any person from selling or keeping open shop for retailing, dispensing or compounding specified poisons or from using the title "chemist and druggist", or "chemist", or "druggist", or "pharmacist", or "dispensing chemist", or "druggist", unless registered by the Pharmaceutical Society. Up to 1919 the latter society not only fulfilled its statutory obligations of examining and registering but it also looked after both the professional and trading interests of pharmacists. In consequence of the judgment in a test case in 1920 the Retail Pharmacists' Union was established, to which were transferred all employers' functions and those of negotiating with the Government regarding the National Health Insurance Act.

Up to the formation of the Institute of Physics in 1920 the physicist had scarcely been recognised as one of the professions, being mainly confined to the universities. The increasing demand for physicists in industry led to the formation of the Institute, which differs considerably in constitution from the Institute of Chemistry. Members of any of five participating societies, which are study associations, can become ordinary members, but the corporate members in whom authority is vested consist of fellows and associates who must have passed either the examination of the Institute or an equivalent examination. Fellows in addition must have had five years' experience. There are 600–700 corporate members and the Institute of Physics has a much more effective command of the profession than has the Institute of Chemistry.

The emergence of the true patent agent possessing a skill partly legal and partly scientific is of comparatively recent date, and the number of qualified patent agents in Great Britain and Ireland is only 343. Since, however, salaried employees in a patent agency are not required to register, there are many qualified persons who have fulfilled all the requirements but have not proceeded to registration. A register of patent agents was established by the Act of 1888, but effective protection was only conferred by the subsequent Patent and Designs Act of 1919, which lays it down categorically that "no person shall practice . . . as a patent agent, unless . . . he is registered". The register is kept by the Institute of Patent Agents and admission is confined to those who have passed a preliminary, an intermediate and a final examination conducted by the Institute. Candidates for the final examination must have served for five years in the office of a registered patent agent, although articles are not obligatory and some exception is granted to those who have graduated at a university or spent a specified time at an approved technical college, or an approved profession or industry or on the examining staff of the Patent Office. In spite of its important educational duties, the Chartered Institute of Patent Agents is a voluntary association and only about two-thirds of the registered patent agents are members.

The recently published work by Prof. A. M. Carr-Saunders and Mr. P. A. Wilson* on the growth and position of the professions, on which the above remarks have been based, is a welcome and valuable attempt to fill a serious gap. The first part gives a survey of the present position of the recognised professions and of other occupations with more or less definite claims to be recognised as professions, and forms an invaluable reference work with regard to qualifications, numbers of practitioners, salaries or positions obtainable in a wide range of professions.

Special interest is attached to the sections dealing with architects and with teachers, one on account of the recent efforts to obtain a registration which issued in the Architects (Registration) Act of 1931, the other on account of the growth of unity in a profession formerly separated by deep-seated jealousies and also on account of the influence of widespread State employment leading to what is in effect a State register of teachers. So, too, the analysis of the conditions which led to public accordance of professional status to the civil service and to local government service, and of those again which prevail in the mercantile marine or among mine managers, are invaluable to all scientific workers who seek to understand the place and functions of professionalism in modern society and to assess the contribution which registration can offer alike to the advance of the professions or of the State they serve.

Taxonomy and Evolution

By DR. W. H. LONGLEY, Marine Biological Laboratory, Tortugas, Florida.

TEN years ago Dr. J. C. Willis developed in his work "Age and Area" his discovery of the existence of an unexpected order in Nature revealed by statistical analysis of selected data of taxonomy. Prof. Bateson expressed keen appreciation of this discovery in a review of the work in NATURE[1]. The sign of order represented was, in Bateson's judgment, highly significant and is the central fact to which the present contribution is related.

In the great natural groups of organisms—the larger families and orders—the statistical distribution of genera by size is approximately the same in all cases; or, to put it in other words, the curve of genera plotted against the number of their species is always of the same general form. This suggests at once that the process of evolution occurs according to law. Indeed, only if the naturalist's conception of genera and species is without justification in the order of Nature itself, or if his classification of material given by Nature is grossly inadequate, may the direct inference be avoided. But, letting the necessary inquiry this suggests rest for the moment, is there independent reason for supposing the process of differentiation of genera and species of organisms may occur according to law?

Manifestly such law as is suggested by Dr. Willis's discovery is one of a statistical sort, a description of the outcome of the evolutionary process as a whole and without regard to detail—a law, indeed, of the general order of the gas laws of physics, where the individual is quite lost to sight. If it be urged that such laws do not deal with underlying truths, it may be admitted at once that they are not exhaustive accounts of the events in systems of which they treat: but they are still laws, and laws, too, of a high order of importance.

The laws of gases (with similar statistical laws) have, in fact, served as the foundation, from one point of view, of our modern industrial civilisation, with all that it entails. If to know how things go, on the whole, with molecules in the gaseous systems they compose, has shown itself so significant a matter, we may believe that the like knowledge of what is involved in the making of genera and species will justify itself. It requires no lively imagination to foresee some of its effects upon our thought, where its important application will chiefly lie.

To consider the gas laws further: these are generalisations empirically established and the basis upon which the kinetic theory of gases rests. It is from them that we derive our idea that the normal gas is a system of ultra-microscopic particles, active and acting at random, incapable of reproduction and variation, capable of exerting an influence upon one another measurable at last as pressure against the weight of a column of supported fluid.

Now clearly there is no theoretical reason why there might not be systems of units differing from molecules in few or many respects, but still active and acting on one another at random, and on that account having among their laws some of the form of the gas laws. Such systems might be composed of macroscopic, as well as of ultra-microscopic units, units capable of exercising some other influence upon one another than that measurable after the precise fashion of gas pressures, units capable of varying or of increasing their number by some sort of reproductive process, or of at once reproducing and varying.

To express such ideas is only to suggest that the kinetic theory of gases is capable of generalisation, and of being applied, *mutatis mutandis*, to a variety of systems, real or imaginary: call them 'kinetic systems', systems the units of which, whatever they may be, are active and act upon others of their kind at random.

Such systems as are proposed do, in fact, exist. 'Glowing gases' are an example. These obey the gas laws but their units are variable. Defective as it may be in detail, Bohr's schematic representation of the structure of the atom and of what is involved in the absorption and release of more or fewer quanta of energy has made this a matter of common knowledge. More still, if the atom's power to vary is exercised, so to speak, under the control of pressure in the glowing gas, the law of distribution of energy in the line spectrum will —when it is made out—prove to be one from which, if it had been first formulated of gas laws, Boyle's, Avogadro's and others might have been derived by inspection. It will be the master-law of the system.

Populations of a single sort of organism, growing under such conditions as are maintained for determining their law of increase, are also kinetic systems in the sense defined. Their law of growth is a master law from which laws of the form of the gas laws may be derived by inspection[2]. They are clearly systems of units, active and acting at random upon one another, but macroscopic ; for practical purposes incapable of effective variation within the life of the experiments ; capable of reproduction, and exerting an influence upon one another measurable as an effect upon their proportional rate of increase as they grow.

To avoid the inference, it is necessary to disprove the premises from which it is deduced by logical process. In an attempt to invalidate the law of growth of populations, it is as little to the point to refer to unanalysed experience in the field as it would be to cite the wavering course of a mote in the sunbeam in contravention of the laws derived for bodies falling *in vacuo* under the influence of gravity. In each case advanced as exceptional, the fundamental law is undoubtedly momentarily obeyed.

Evolution is the process of differentiation of a compound population, a population composed of more than one sort of thing, one in which the unit is not the individual but a natural group of individuals related by descent. So Dr. Willis's discovery suggests only that besides the three sorts of kinetic system definitely recognised—and with recognised laws—there is a fourth, the compound population, of which the characteristic process of differentiation also occurs according to law, the master law of this kind of system.

To reach a final decision regarding the soundness of these suggestions, one may first validate the taxonomist's conception of genera and species as groups objectively existing[3]. The empirical curves of genera plotted by size may then be determined as accurately as possible. In course of this work, it appears that in no great group of organisms are known species a representative sample of the world population[4]. The curves therefore change as knowledge grows respecting the groups to which they individually refer. But as they change, they tend to assume the same limiting form, which is a function of the curve of normal frequency.

Space does not permit the argument to be carried here to its logical conclusion. This requires that it be shown that the curve derived from analysis of the data of taxonomy is what theoretical considerations indicate it should be. But even if it be left for the moment an open question whether the law of evolution is the law of differentiation of a particular sort of kinetic system, the existence of the law as such justifies the confidence expressed in the validity of the species conception one finds so commonly in some sense in the writings of systematists, and nowhere more plainly than in contributions by the scientific staff of the British Museum (Natural History).

The light it throws upon existing order in Nature—specifically in the matter of evolution—establishes taxonomy as a science, its place among the biological sciences being comparable to that of astronomy among the physical sciences. It deals with the products of a process as nearly cosmic, as nearly transcending the resources of the experimental method, as anything biology knows.

Iraq Petroleum and Pipe-Line

AS M. Victor Forbin so graphically explains in a recent article on "Le Pétrole de Mésopotamie et son Pipe-Line" (*La Nature*, No. 290, pp. 253–262, March 15, 1933), the petroleum industry of Iraq is historically the oldest and commercially the youngest in the world. In spite, however, of sundry biblical and legendary references to natural resources, negotiations for the acquisition of oil land were not opened until the beginning of this century, and no definite concessions were granted until 1928, when the Iraq Petroleum Co. was founded. Even at this stage, further development of the petroleum industry in Iraq was not assured, for it had yet to be discovered whether the seepages were in fact indicative of untapped resources or merely the dregs of ancient pools.

In 1925, twelve enterprising geologists of various nationalities set out on an expedition to Iraq. Undaunted by extremes of temperature, hostile attacks from nomadic tribes and the numerous problems of structure peculiar to that country, they selected ten sites for testing purposes. The first well drilled in one of these sites, Baba Gurgur, near Kirkuk, was the scene of a great disaster. The boring unexpectedly pierced a dome, of which there had been no surface indication, and liberated a gusher of oil which had finally to be diverted into channels and set on fire in order to prevent further catastrophe. Additional precautions were necessarily taken in drilling subsequent wells on this site, with the result that a prolific production was obtained. In fact, so prolific is the production that to fulfil an annual contract of 4 million tons, only fifteen of the thirty wells drilled need be tapped. Moreover, as Kirkuk is the only one of the ten selected sites which has been developed, the future supply of Iraq oil is potentially enormous.

The pipe-lines which run from the oilfield to the Mediterranean sea are among the most remarkable of their kind. There are longer lines in the United States, but none required greater engineering skill and endurance. Practically the whole line is laid through barren inaccessible territory and the workers are obliged to make roads, huts and means of communication before they can begin on actual construction. Moreover, they have frequently suffered from shortage of drinking water and have had little or no protection against extremes of heat and cold.

The proposed pipe-line course was modified several times in the early stages of the project, but the final form is that of the letter Y. The pipes run in a double track from Kirkuk, across the Tigris to the Euphrates where they fork, one line northward and the other southward. The former is the shorter and easier route and terminates at El Mina, near Tripolis. The southern line, which has proved much more difficult to lay, is not yet completed, but will eventually be carried to the Bay of Acre near Haifa. Two thousand kilometres of steel tubes, representing a weight of 116,000 tons, have been laid at depths varying from one to several metres, through the most difficult territory in the world, in order to accomplish this engineering feat. Moreover, 500 Europeans and Americans and 6,000 natives have been employed in the construction. The cost of laying the lines is naturally considerable, having regard to the peculiar difficulties which had to be overcome, and the question arises as to whether the construction is, and will be, in the future, economically worth while.

In the first instance, Tripolis and Haifa are geographically better situated for the exportation of petroleum than the ports of Russia and Roumania, or even of the New World, for they are considerably nearer the chief centres of importation. Cost of transport will therefore be low in comparison with that paid by rival countries. Cost of production is likewise low owing to the large quantity of oil procurable from each well, the vast dimensions of the oilfields, and the ease with which drilling operations are effected. It is therefore conceivable that the oil of Iraq will in the future be the cheapest and most accessible in the world, although it originates in, and has to flow through, such apparently impossible territory.

Obituary

HARRIET BROOKS (MRS. FRANK PITCHER)

HARRIET BROOKS (MRS. FRANK PITCHER), who died in Montreal on April 17, was well-known in the years 1901–5 for her original contributions to the then youthful science of radioactivity. A distinguished graduate of McGill University, she was one of the first research workers with Prof. (now Lord) Rutherford in Montreal. She observed that the decay of the active deposit of radium and actinium depended in a marked way on the time of exposure to the respective emanations and determined the curve of decay for very short exposures. This work, which was done before the transformation theory of radioactive substances was put forward, assisted in unravelling the complex transformations which occur in these deposits. With Rutherford she determined the rate of diffusion of the radium emanation into air and other gases. These experiments were at the time of much significance, for they showed that the radium emanation diffused like a gas of heavy molecular weight—estimated to be at least 100.

Miss Brooks entered the Cavendish Laboratory, Cambridge, in 1903 and continued her radioactive investigations. In a letter to NATURE of July 21, 1904 (vol. 70, p. 270) she directed attention to a peculiar type of volatility shown by the active deposit of radium immediately after its removal from the emanation. In the light of later results of Hahn and Russ and Makower in 1909, it is clear that the effect was due to the recoil of radium B from the active surface accompanying the expulsion of an α-particle from radium A. This method of separation of elements by recoil ultimately proved of much importance in disentangling the complicated series of changes occurring in the radioactive bodies.

After her marriage to Mr. Frank Pitcher of Montreal, she gave up her research work but took a strong interest in university affairs. In this she was aided by her family ties, for one sister is the wife of Sir Charles Gordon, a prominent supporter of McGill University, and another the wife of Prof. A. S. Eve, professor of physics in McGill University. A woman of much charm and ability, she was a welcome addition to any research laboratory and left in all who met her a vivid impression of a fine personality and character. R.

DR. H. BASEDOW

THE recent death of Dr. Herbert Basedow at the age of fifty-two years, which is announced in a dispatch by Reuter from Adelaide, will be deeply regretted by anthropologists in Great Britain, where his persistent and courageous efforts on behalf of the Australian aborigines, which brought about the allotment of an extensive reservation for those of the central area, were widely appreciated and received influential support. Since the death of Sir Baldwin Spencer, Dr. Basedow had been generally recognised as the first authority on the aborigines of Australia.

Dr. Basedow was born in Adelaide on October 27, 1881, the son of a former minister of education, and was educated at Prince Alfred College and the University of Adelaide, studying later at the Universities of Göttingen, Heidelberg, Breslau and Zurich. He entered the South Australian Geological Service; but in the course of a number of expeditions to the interior of Australia, he became interested in the Australian aborigines, both scientifically and from the practical point of view of their protection from the deleterious influences of contact with civilisation. On several occasions he lived among them for considerable periods for purposes of study. In 1911 Dr. Basedow was appointed Chief Protector of the Aborigines for the Federal Government in the Northern Territory and he was also Medical Commissioner of Aborigines under the South Australian Government.

Basedow had achieved a considerable reputation by his contributions to scientific periodicals, including the publications of the Royal Anthropological Institute of Great Britain. This he consolidated by his chief work "The Australian Aboriginal" published in 1925, a record of careful observation, which also showed considerable originality in interpretation. He showed himself a vigorous controversialist in the local press on behalf of the aboriginal. In 1928 he undertook his most important piece of zoological and anthropological research when he led an expedition to Arnhem land. On his retirement from his official position, he entered business and politics and was elected a member of the Adelaide legislature in 1927.

WE regret to announce the following deaths:

Major W. C. Ball, O.B.E., superintendent of the Chemical Department, Porton, on June 9.

Mr. William B. Bannerman, known for his work on local archæology especially of Kent, Surrey and Sussex, on June 6.

Prof. W. L. Elkin, emeritus professor of astronomy in Yale University and director of the Yale Observatory from 1896 until 1910, on May 29, aged seventy-eight years.

Sir Walter Morley Fletcher, K.B.E., C.B., F.R.S., secretary of the Medical Research Council, on June 7, aged fifty-nine years.

Dr. J. G. Hibben, formerly president of Princeton University, who has published several textbooks on logic and psychology, on May 16, aged seventy-two years.

News and Views

The World Economic Conference

HIS MAJESTY THE KING in opening the World Economic Congress on June 12 proclaimed his satisfaction that such a gathering had been possible and expressed his confidence that this common endeavour would lead to beneficial results. Unlike that of 1927, the Conference is a Conference not of officials but of Governments, in fact of all the Governments of the world, since it includes the representatives of some sixty-six nations. The magnitude of the task confronting the Conference and the difficulties involved are great but, as His Majesty stated, there is evidence of a real desire to reach agreement. All nations are suffering from a common ill as is shown only too clearly by the rise in the figure of unemployment. In appealing to all the representatives to co-operate for the sake of the ultimate good of the whole world, in the face of a crisis which all realise and acknowledge, the King stated that it cannot be beyond the power of man so to use the vast resources of the world as to ensure the material progress of civilisation. No diminution in these resources has taken place. On the contrary, discovery, invention and organisation have multiplied their possibilities to such an extent that abundance of production has itself created new problems. There has come also a new recognition of the interdependence of nations and of the value of collaboration between them. Therefore, as His Majesty stated, there is now an opportunity of harnessing this new consciousness of common interests to the service of mankind. His Majesty's speech and also that of Mr. Ramsay MacDonald, who followed the King, were broadcast by the British Broadcasting Corporation, and a record of the King's speech was made by His Master's Voice Company.

Sir Prafulla Chandra Rây, C.I.E.

SIR P. C. RÂY stands alone amongst Indian men of science not only on account of his scientific attainments but also for his public activities. In December last his colleagues and former students took advantage of his seventieth birthday to show their appreciation and esteem by presenting him with a congratulatory address in which they announced that a considerable sum had been subscribed which would be applied to assist indigent students. The Indian Chemical Society has dedicated a handsome commemoration volume to its first president and it has thus enabled Sir Prafulla's friends in other countries to show their appreciation of his services to science ("Sir Prafulla Chandra Rây". Seventieth Birthday Commemoration Volume. *Journal of the Indian Chemical Society*, Special number. Pp. vi+363. Calcutta: Indian Chemical Society, 1933.) This volume of more than 300 pages contains 36 papers and, although the majority of these are naturally by Indians, chemists from Great Britain, America, Germany, Austria and Switzerland have also contributed. Pride of place is fittingly given to a paper by the president of the Chemical Society, Prof. G. T. Morgan, who, with Dr. F. H. Burstall, gives an interesting account of recent high-pressure work which has been carried out at the Chemical Laboratory, Teddington, on the dehydrogenation of pyridine with anhydrous metallic chlorides. One of the products of the reaction, 2 : 2′-dipyridyl, yields particularly important co-ordination compounds (Nature, 128, 31, July 4, 1931).

The two other contributions from Great Britain are by Prof. M. W. Travers and Prof. F. G. Donnan, the former discussing the pyrolytic condensation and decomposition of ethane in the presence of hydrogen, whilst the latter presents a short but stimulating note on the thermodynamic functions of radiation. Students of the chemistry of the polysaccharides will welcome a valuable résumé of recent investigations in this field from the pen of Prof. H. Pringsheim. Another paper of great interest by Prof. Franz Fischer summarises the valuable work on the utilisation of coal gas which he has carried out during the past few years. As would be anticipated by those who have followed the trend of chemical research in India, the majority of the papers by Sir Prafulla's former students are on physico-chemical themes and are of interest mainly to the specialist. Prof. M. N. Saha has, however, written a remarkably able review entitled "Spectroscopy in the Service of the Chemist". The contributions to this commemoration volume reach a high standard and augur well for the future of the schools of chemistry in India of which Sir Prafulla may with justice regard himself as the founder.

Mr. Pierre Chevenard

The "Société d'Encouragement pour l'Industrie Nationale" awards annually a special medal with the effigy of an eminent person in science or arts to a French or foreign author whose work has had the most effect on the progress of French industry. The medal for 1932 bears the effigy of Prony and has been awarded by the Committee of the Society dealing with mechanical arts to M. Pierre Chevenard, a mining engineer of the Mining School at Saint Étienne. Born in 1888, M. Chevenard has, since 1910, worked in the research laboratory at Imphy of the metallurgical works of Commentry, Fourchambault et Décazeville. One of his most important papers deals with an experimental research on iron, nickel and chromium alloys, but he is especially known for elaborating devices for the examination of very small quantities of alloys. With small samples a homogeneous temperature is secured throughout the piece, this being important for quick and reliable measurements, and M. Chevenard was able to examine the physical properties of alloys over a wide range of temperature. His differential dilatometer, galvanopyrometer, and apparatus for the examination of the mechanical properties of alloys, are widely used all over the world. Besides purely scientific research, M. Chevenard has contributed a great deal to the production of special alloys at Imphy, such as M. Ch. Guillaume's invar, elinvar and the A.T.V. ferro-nickel alloy.

Concealing Coloration of the Tapir

The birth at the Gardens of the Zoological Society of London, last week, of a Brazilian tapir is worth recording, since it will afford visitors to the Gardens an opportunity of examining one of the most striking types of 'protective', or 'concealing coloration' in young mammals to be found anywhere. It takes the form of numerous longitudinal white stripes on a black background. The stripes tend to break up into short bars and spots on the flanks, while the legs are obliquely striped. The face is spotted. This coloration is the more interesting because the young of the Malayan tapir is coloured after a closely similar fashion; while the adults of the two species are as unlike as could well be. In the young Malayan species the spots on the face are more numerous and distinct, while the stripes down the sides are rather more sharply defined and less broken up on the lower flanks. As the animal approaches maturity these markings fade out in a very curious way. As the great white area of the body behind the withers gradually shows up, the stripes fade out; but they persist far longer on the black fore-quarters and the face. The strange coloration of the adult Malayan tapir affords another striking example of 'concealing coloration', since when asleep in dry boulder-strewn water courses these animals look themselves like boulders, the white area forming the summit while the black fore-quarters and legs simulate the deep shadows cast by such boulders in the intense sunlight.

Theory in Modern Physics

The leading idea of Prof. A. Einstein's Herbert Spencer lecture, entitled, "The Method of Theoretical Physics", delivered at Oxford on June 10 was the relation between experience and reason in the domain of physics. The Greeks, he said, perfected a logical system in which, considered as such, no flaw could be found. But it was a closed system; and its concepts and laws, though for long believed to be derivable from the data of experience, were entirely a creation in the mind of the theorist. The practical success of theory in the hands of Newton obscured during the eighteenth and nineteenth centuries the want of correspondence, now evident, of pure theory with the results of experience. But though the view that prevailed for so long must be discarded, Prof. Einstein believes it to be possible for the theorist to construct a system that will be a true model of reality. Experience cannot give the answer to the problem of Nature, but it can suggest the methods which will enable the theorist to arrive at a solution.

Inadequacy of Economic Sanctions

In a recent issue of the *New Commonwealth*—a journal devoted to the promotion of international law and order—Dr. J. J. van der Leeuw discusses the inadequacy of economic sanctions. The greater the measure of disarmament, he writes, the greater the need for sanctions. Complete disarmament, though this is the only safe basis for a lasting peace, is unthinkable without safeguards against aggression by an improvised attacking force. Such safeguards, however, must not merely consist of coercive measures against an aggressor nation; they must be a protection against aggression. It is in this respect that economic sanctions fail whether they take the form of an economic and financial boycott of the aggressor or that of a regular blockade. (1) They come too late; they can only be applied as a corrective; they do not protect against aggression. (2) Economic sanctions are notoriously slow in their application. (3) They are a double-edged weapon, striking at international trade and punishing the innocent with the guilty. (4) Economic sanctions are powerless against nations which can, if need be, form self-sufficient economic units, such as the United States to-day and the U.S.S.R. to-morrow. Dr. van der Leeuw contends that an international police force alone would make complete disarmament possible, since it would provide security against aggression, not merely coercion afterwards. Each nation would contribute its quota to the world police and, having done so, would not be further involved.

Old Gaza

SIR FLINDERS PETRIE's letter to the *Times* of June 2, announcing that it would not be possible this year to hold the usual exhibition of material from the Palestinian excavations of the British School of Archæology in Egypt, will give rise to much regret. The members of the school, Sir Flinders reports, this year have been engaged for the third season in succession in the excavation of Old Gaza (Tell el Ajjul), where the earliest palace, dated at about 3200 B.C., discovered last year, awaited clearance. It now appears that the foundations were laid in a rectangular block about 127 ft. from north to south and about 166 ft. in length. The buildings enclosed a large square courtyard with chambers on three sides, but with an enclosing wall only on the fourth, or south, side. Egyptian influence is strongly marked in a number of small objects and a finely carved stone head from a funerary jar, which is earlier than any from Egypt. Greater interest, perhaps, is attached to several objects which may point to the place of origin of the Syrian invaders. These were a bronze dagger with raised veins, very similar to one found last year, which is a Caucasus type, and two forms of toggle which belong to the same area. The burial was early, while from a superimposed burial came a scarab which cannot be later than the xith dynasty. South of the palace area massive buildings were uncovered in a sand dune which yielded fragments of painted pottery, similar to that found last year, of which the origin is still obscure, although northern Syria, Armenia or Cappadocia are indicated. The buildings with which this pottery was associated were of the age of the first and second palaces—viith and xiith dynasties. Other parts of the Tell have been excavated, yielding nearly two hundred types of pottery, and the family tomb of an Egyptian governor, which indicates a continued Egyptian occupation from the time of Akhen-aten to Rameses II. A second gold torque ear-ring of Irish pattern occurred in an xviiith dynasty level.

Local Archæological Observation in the United States

USEFUL information relating to local archæological sites and discoveries, which might otherwise be disregarded as unimportant and lost to sight, is being recorded through a system of local correspondents and investigators inaugurated by Science Service (Washington, D.C.). Naturally the information varies considerably in value and interest; but as time goes on, the organisation should serve a useful purpose in preserving data which will assist in determining the character, distribution and relation of the Indian cultures which had become extinct before the days for which records of the tribes are available. An instance in point is afforded by a communication recently received by Science Service from Mr. William E. Baker of Boise City, Oklahoma, who describes Indian ruins on the south bank of the Beaver River, four miles south of Optima, Oklahoma. The ruins are of the type known as 'slab house', being constructed of stone slabs, set on edge. Before the depredations of neighbouring builders, they covered a site of several acres. Their artefacts, flint arrow points, drills, snub-nosed scrapers, and bone implements, are such as have a wide distribution in the Plains, being found in the western half of Kansas, the panhandle of Oklahoma and of Texas. They have also been found at Pecos Pueblo. Mr. Baker differentiates two cultures, partly on stratigraphical grounds. The earlier is characterised by a small arrow point with right-angled notches, which is associated with pottery of the Plains type. In the later the arrow point is large and has diagonal notches, but pottery is absent. The former was probably partly agricultural—a view supported by a suggestion of irrigation and the discovery of kernels of corn—the latter nomadic. This order and association has been found by Mr. Baker over a wide local area while the cultures are related to types described by Dr. W. K. Moorehead on the Arkansas River and Dr. A. W. Kidder at Pecos Pueblo. Mr. Baker suggests that there was a widely distributed semi-agricultural population spread over the Plains before the coming of the Spaniards, when the introduction of the horse made possible a nomadic life dependent on the buffalo.

Oil Reserves and Production

SOME interesting figures of oil reserves and past production to date were given by Mr. V. R. Garfias to the American Institute of Mining and Metallurgical Engineers recently. According to this authority, the proved oil reserves are estimated at more than 24 billion barrels and the world production of oil to date aggregates nearly 23 billions. Of the realised reserves, 61 per cent are located in the American continent, while Russia, Iraq and Persia account for 33 per cent. Science Service of Washington, D.C., states that the American reserves, when compared to the probable future consumption in the United States, will prove inadequate to meet demands for more than a few years, unless there should be a pronounced falling off in demand. It is considered that the Venezuelan, Iraq and Rumanian fields will in the future become, in varying degrees, potential sources of instability in the world's oil trade, but in this connexion it would seem that the growing importance of an ever-increasing Russian production has not been assessed at its true significance. Further, Mr. Garfias's figures do not consider estimates of potential oil reserves but cover only the world's oil supplies estimated to remain underground in the present-known producing fields and their anticipated extensions.

Electric Trolley Omnibuses

ABOUT twenty years ago, electric tramways had no serious rivals for street passenger traffic. As they are doing to-day, they were then carrying a very large number of passengers. The advent of petrol and electric omnibuses was not considered as a serious menace to their prosperity. They would doubtless be useful in those districts where the cost of installing tramway track was prohibitive. In a paper read to a joint meeting of the Institution of Electrical Engineers and the Institute of Transport on April 10, C. J. Spencer described the progress made in developing electric trolley omnibuses during the last twenty years and discusses the general problem of street passenger traffic. The great advantage of a trolley omnibus is that it can use a series electric motor—the most perfect of all traction motors. It gives its maximum torque when starting and can carry an overload of a hundred per cent for several minutes without damage.

THE War hindered the development of the trolley bus. Ten years ago, only 47 route miles were operated in Great Britain. Last year the number had increased to 256 miles and numerous extensions are being planned. The modern electric bus is little more than an adapted petrol bus; the engine and gear box have been removed, an electric motor substituted and a trolley collecting gear bolted on the roof. The weight of the motor used for trolley bus operation is only 12 lb. per horse power. This compares with 70 lb. per horse power in pre-War days. In the early buses, two motors of 20 h.p. were used in each bus but now a single 80 h.p. motor is used. This is capable of withstanding the roughest usage. The London United Tramways Co. recently converted 17 miles of route between Twickenham and Wimbledon into trolley bus operation. At the start, many complaints were made by possessors of radio sets of extraneous noises in their apparatus due to 'interference' by the buses. Thanks to the help of the General Post Office and the British Broadcasting Corporation this trouble has been practically overcome. On busy routes, evolution of design has led to a continual increase in the size of the vehicles.

National Research Council of Canada

THE fifteenth annual report of the National Research Council of Canada (Ottawa) surveys the activities of the Council in the period 1931–32. The demand for scientific assistance from industrial groups was greatly increased and, during the year, the Council considerably extended its direct relations with industry, a number of associate committees having been formed as a result of the Council's effort to relate itself with industrial development. The Council is largely echoing the views of the Advisory Council for Scientific and Industrial Research in Great Britain in asserting, and demonstrating from its own experience, that science will not occupy its proper place until the industrialist is ready, not merely to admit the possibilities of research and accept its assistance, but also to co-operate fully and on a confidential basis with workers in the scientific field. The report summarises the activities of the laboratory divisions as well as the activities of associated committees and the reports of assisted researches. From this wealth of information it is impossible to select more than a few points illustrating the scope of the investigations covered. Both in the Division of Chemistry and in that of Biology and Agriculture, considerable attention has been devoted to chemicals and herbicides as well as to the fire hazards attached to their use. Synthetic rubber and resins and the efficiency of detergents are other questions investigated by the Division of Chemistry, while the Division of Physics and Engineering has been concerned with aeronautics, locomotive research, and fire hazards of oil burners. Associate committees have dealt with a wide range of problems of animal diseases, field crop diseases, coal classification and analysis, engineering standards, gas research, grain research, leather, magnesian products, oceanography, radio research, tuberculosis, weed control, and wool.

Agricultural Societies

THE gain to agriculture from the activities of the various agricultural societies which have flourished during the last two centuries must be enormous. These associations, supported by landlord enthusiasts bent on improving their estates and raising the standard of farming, have spread agricultural knowledge by their publications, by the offer of prizes for information or practical achievement, and by their shows of implements and live-stock. They have continually fostered scientific inquiry into the technical problems of farming, and in their journals are to be found the successive landmarks of agricultural progress. On June 8, 1723, was founded the earliest association of this kind in Scotland under the title "The Honourable the Society of Improvers in the Knowledge of Agriculture in Scotland". Its members were certain noblemen and gentlemen who were impressed by the backward state of farming at this period. The Society was concerned with the collection and dissemination of the best agricultural information. It advised members on their farming problems; on cultivations, including the new horsehoeing husbandry of Jethro Tull, on sheep folding and on cattle feeding. Under the last heading the recommendation that the cattle be "not less than seven years old" before feeding commences, reads rather strangely in these days of 'baby beef' and rapid turnover. On the other hand, few stockmen will find fault with this:—"Be sure to prepare a careful hand to attend the feeding of them, for upon this depends the whole success of the attempt". The Society concerned itself with fisheries and manufactures in addition to its main objective. It did not survive the upheaval of 1745, but for twenty years supplied a need which more permanent societies were later to satisfy.

Research in Germany

THE issue of *Die Naturwissenschaften* for May 26 is devoted to the work of the Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften and extends to more than eighty pages. The year ending March 1933 has been a difficult one for the society, and the hope is expressed that the Government will in the future be able to afford it more financial support. Its membership is now 786, a fall of more than 40 on the year. Its headquarters—Harnack House—provides accommodation for the meetings of more than thirty societies in addition to those of its own sections, daily meals for 160 scientific workers, and has put up for short stays 230 visitors during the year. Evening lectures, by distinguished members of the staff, have been given both at headquarters and in other towns of Germany as in previous years. In addition to outline reports of the work of each Institute, lists of papers published by the staffs are given, and both show how much the society is doing by scientific research to increase the welfare of Germany and to maintain its position amongst those bent on "improving natural knowledge".

Annual Meeting of the French Chemical Society

THE French Chemical Society is holding its annual general meeting in Paris on June 15–17; at the same time it is commemorating the bicentenary of the birth of Priestley. Among the distinguished foreign visitors at the meeting are Sir William Pope, professor of chemistry in the University of Cambridge, who has been asked to preside over the opening meeting; Prof. Morgan, president of the Chemical Society; Prof. H. E. Armstrong; Prof. J. Böeseken, professor of organic chemistry in the Technical High School at Delft, who is speaking on the configuration of the polyalcohols; and Prof. E. Späth, professor of chemistry in the University of Vienna, who is discussing recent syntheses of alkaloids. An address on "Priestley and his scientific Work" was to be given on June 15 by Prof. C. Matignon, professor of inorganic chemistry in the Collège de France, and president of the Society. Priestley, by a decision of the National Council, was made a French citizen and was a member of the Academy of Sciences.

"Empire Forestry Handbook"

THE Empire Forestry Association has recently published a new edition of the "Empire Forestry Handbook" (Empire Forestry Association, Grand Buildings, Trafalgar Square, London. 5*s*.). The handbook contains much useful information, including a list of the officers and members of the Empire Forestry Association, and forestry officers serving in different parts of the British Empire. This is followed by a digest of education and research in forestry throughout the Empire, including lists of the universities and research institutes which contain forestry departments, together with the heads of departments and research workers. A list of forest periodicals is appended. The section on forest resources of the Empire contains a wealth of useful statistics concerning forest areas, and production, exports, etc., of conifers and hardwoods. The "Handbook" concludes with a list of the trade and botanical names of Empire timbers.

Lister Institute of Preventive Medicine

THE report of the governing body, presented at the annual general meeting of the Lister Institute of Preventive Medicine on May 24, gives a survey of the scientific work carried out during the year in the various departments. This includes studies on the viruses of variola, vaccinia, and varicella by Drs. Ledingham and Amies, on the typhus group of diseases by Dr. Felix, and researches on nutrition and vitamins in the Division of Nutrition under Dr. Harriette Chick. The nature and function of phosphoric esters formed during alcoholic fermentation have been studied by Prof. Robison and his collaborators. The National Collection of Type Cultures is housed in the Institute, and more than 5,000 strains of bacteria and fungi have been distributed to workers at home and abroad, and some 200 types have been added to the collection. The total expenditure for the year was £43,258, and the excess of income over expenditure £10,362.

National Institute for Research in Dairying

THE annual report for the year ending July 31, 1932, of the National Institute for Research in Dairying, University of Reading, which has only recently been issued, gives a summary of the research work carried out in the various departments. This includes a study of typical English milk, experiments on the feeding of young dairy cattle, and details of schemes for controlling the cleanliness of milk delivered by producers to retailers. Dr. H. Davenport Kay has been appointed to succeed the late Dr. Stenhouse Williams as director of the Institute. The financial position remains substantially the same as in the previous year, and additional income is still needed to stabilise the present position, and without reference to the ultimate needs of the Institute.

Franklin Institute Medals

AMONG the medal awards recently made by the Franklin Institute, Pennsylvania, are the following: Franklin medal, founded in 1914 by Mr. Samuel Insull, of Chicago, and awarded to those workers in physical science or technology whose efforts have done most to advance a knowledge of physical science or its application, to Dr. Orville Wright, of Dayton, Ohio, in recognition of the valuable investigations carried out by him and his brother, Wilbur, from which they obtained the first reliable scientific data concerning the principles of flight and the design of aeroplanes; and also to Dr. Paul Sabatier, dean of the Faculty of Science of the University of Toulouse, in recognition of his contributions to the general field of chemistry and especially to organic chemistry, in which he discovered the catalytic activity of finely divided common metals and devised methods for their use in science and industry; Elliott Cresson medal, founded in 1848 by Mr. Elliott Cresson, to Señor Juan de la Cierva, of London, in consideration of the original conceptions and inventive ability which have resulted in the creation and development of the autogiro.

Announcements

PROF. F. G. DONNAN, professor of general chemistry in the University of London, was elected an honorary member of the Bunsen Society at its thirty-eighth annual meeting held at Carlsruhe on May 26-28.

PROF. E. W. MACBRIDE, professor of zoology in the Imperial College of Science and Technology, has been appointed by the Development Commissioners to be chairman of their Advisory Committee on Fishery Research in succession to the late Prof. G. C. Bourne.

THE following appointments in the Colonial Agricultural Service have recently been made by the Secretary of State for the Colonies:—Mr. A. M. Gwynn, to be entomologist in the Department of Agriculture, Nigeria; Mr. C. L. Willding-Jones, to be assistant superintendent of agriculture, Gold Coast.

IT is announced in *Science* of May 19 that the Rumford medal of the American Academy of Arts and Sciences has been awarded to Dr. Harlow Shapley, director of the Harvard College Observatory and Paine professor of astronomy in Harvard University, for "researches on the luminosity of stars and galaxies".

IT is announced by Science Service that Commdr. Jerome Clarke Hunsaker, now vice-president of the Goodyear-Zeppelin Corporation, Akron, who designed the first modern airships produced in the United States, has been awarded the 1933 Daniel Guggenheim medal. Commdr. Hunsaker introduced aerodynamic research into American aircraft design by translating Eiffel's pioneer work and building the first wind tunnel at the Massachusetts Institute of Technology. He designed the *Shenandoah* airship and the first modern non-rigid airships in the United States. Since resigning from the Navy in 1927, he has played an important part in the production of the *Akron* and the *Macon*.

A DISCUSSION on "The Ionosphere", to be opened by Prof. E. V. Appleton, will take place at the Royal Society on June 22 at 4.30 p.m.

THE Masters' memorial lectures of the Royal Horticultural Society will be delivered in the lecture room of the Society's new hall in Greycoat Street, Westminster, on July 18 and 19, at 3.30 p.m., by Prof. V. H. Blackman, on "Plants in Relation to Light and Temperature".

IN 1920, Miss L. Jones-Bateman of Cae Glass, Abergele, presented to the Royal Horticultural Society a valuable silver-gilt replica of the Warwick Vase to be used for the encouragement of fruit production. It is accordingly decided to offer it triennially for researches in the growing of hardy fruits, figs, grapes and peaches in the open or under glass, and it is available for award in 1933. Candidates should submit accounts of their work by October 31 to the Secretary, Royal Horticultural Society, Vincent Square, Westminster, London, S.W.1.

THE life story of William and Caroline Herschel has been compiled from their journals and letters by Lady Lubbock, the granddaughter of Sir William Hershal, and will be published in July under the title "The Herschel Chronicle", by the Cambridge University Press. The book presents so far as possible in their own words, the astronomical discoveries of the Herschels.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An organiser of further education and a principal of the Stratford-on-Avon Technical and Art School—The Director of Education, 22, Northgate Street, Warwick (June 19). A chief sanitary inspector for the Municipal Commissioners, Penang—Messrs. Peirce and Williams, 1, Victoria Street, Westminster, S.W.1 (June 21). A University professor of pathology at the London (Royal Free Hospital) School of Medicine for Women—The Academic Registrar, University of London (June 23). A probationary forest officer for H.M. Forestry Commissioners—The Secretary, Forestry Commission, 9, Savile Row, London, W.1 (June 24). A lecturer in experimental psychology at the University of St. Andrews—The Secretary (June 24). A demonstrator in botany, interested in mycology, at King's College, Strand, London, W.C.2—The Secretary (June 27). A head of the Mathematics and Physics Department of the Liverpool Central Municipal Technical School—The Director of Education, 14, Sir Thomas Street, Liverpool, 1 (July 3). A junior assistant in the Electrical Engineering Department of the Royal Technical College, Glasgow—The Professor of Electrical Engineering (July 10). Examiners in various scientific subjects in the General and Higher School Examinations of the University of London—The Secretary to the Matriculation and School Examinations Council, University of London, South Kensington, S.W.7 (July 21). A professor of economics and commerce, and a professor of education at University College, Hull—The Registrar. A teacher of cookery at the Gloucestershire Training College of Domestic Science, Barrack Square, Gloucester—The Principal. A mechanical engineer for water works for the Government of the United Provinces, India—The High Commissioner for India, General Department, India House, Aldwych, W.C.2. A lecturer in botany at the Midland Agricultural College, Sutton Bonington, Loughborough.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Fine-Structure of the Ionosphere

I WAS much interested in the letter by Messrs. Schafer and Goodall in NATURE of June 3 dealing with the results of their experiments on the radio exploration of the ionosphere in the United States, since an independent set of observations in Great Britain, which are dealt with at length in a paper now awaiting publication, have led to very similar conclusions.

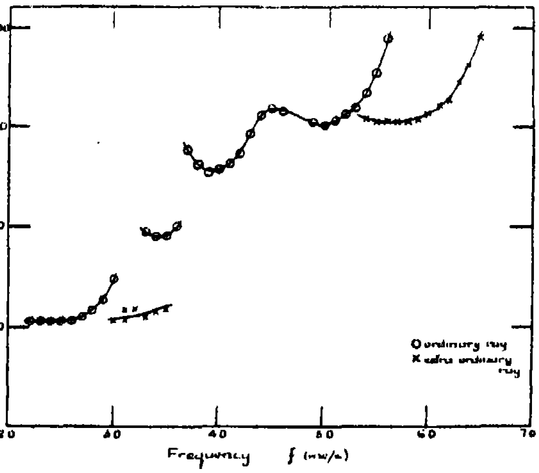

FIG. 1. (P^1, f) curve at 1200, April 8, 1933.

The method[1] used in the British series of observations has been to measure the maximum ionisation content of the various upper atmospheric regions by finding the critical penetration frequencies. Attention has been concentrated on the case of the ordinary ray of the two magneto-ionic components into which the incident wireless beam is resolved due to the influence of the earth's magnetic field. Such penetration frequencies are found from the inspection of a curve illustrating the relation between the equivalent path P^1 of the atmospheric waves and the frequency f. The maximum ionisation content N is then calculated from the formula

$$N = \frac{3}{2}\frac{\pi m}{e^2}f^2$$

where e and m are respectively the charge and mass of an electron and f is the critical penetration frequency.

The following results have been obtained from such determinations made at the Radio Research Station, Slough, in experiments carried out as part of the programme of the Radio Research Board of the Department of Scientific and Industrial Research.

(1) Evidence has been found of the existence of a region of electrification intermediate between the two main regions E and F. (This has already been pointed out by my collaborator Mr. Naismith.[2]) The ionisation in this 'intermediate' region, as it may be called, is usually less than that in region E at noon but, in the early morning hours, as the solar rays begin to ionise successively lower strata of the atmosphere, it is noted more frequently. Our experience in this connexion is therefore different from that of Messrs. Schafer and Goodall.

(2) Evidence of the existence of a protuberance or ledge on region F has also been found, the maximum ionisation of which increases with solar altitude. Region F must therefore be regarded as composite.

A rather unusual (P^1, f) curve illustrating both phenomena is shown in Fig. 1 from which may be deduced the maximum ionisation contents (in electrons per cubic centimetre) as follows: region E, $1{\cdot}8 \times 10^5$; intermediate region, $2{\cdot}5 \times 10^5$; region F ledge, $3{\cdot}8 \times 10^5$; and region F main, $6{\cdot}1 \times 10^5$.

As previously stated, it is not usual in England for the intermediate region to be as strongly ionised as region E, so that the original division of the ionosphere into two main reflecting regions must still be retained. The most frequent daytime variation of ionisation with height appears to be that shown in Fig. 2. The British measurements do not, as do the American series, give the actual heights of the ionisation maxima, but they give the values of the maximum ionisation contents. The relative values of the ordinates of Fig. 2 are therefore approximately correct but not the relative values of the abscissæ.

The British series of observations suggests therefore that there are four main components in the ionosphere caused by the influence of ultra-violet light from the sun. Such a composite structure is not considered unlikely when it is remembered that Pannekoek[3] has shown that the level of maximum ionisation caused by ultra-violet radiation depends on the ionisation potential of the gaseous constituent. It is tempting to associate the four components with the four ionisation potentials of oxygen and nitrogen atoms and molecules, and the suggestion that F^{II} is due in this way to oxygen atoms and F^{I} to oxygen molecules has, indeed, already been made by T. L. Eckersley[4], who independently obtained evidence indicating a dual structure for region F.

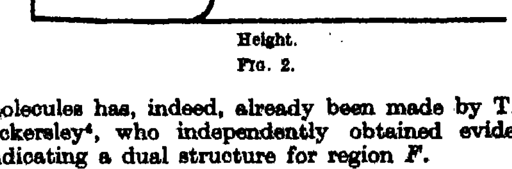

FIG. 2.

Concerning the subject of nomenclature, reasons are given in my paper for adopting the one indicated in the diagram. The suggestion of Messrs. Schafer and Goodall that the intermediate region should be called the M region, while acceptable in other ways, may perhaps lead to confusion in one respect; since an M region reflection might be mistaken for what Ratcliffe and White have, very appropriately, called

M reflections (that is, tracks of waves which have been reflected in succession from region *F*, the upper part of region *E*, and region *F* again before coming back to the ground). For that reason the term 'intermediate region' seems preferable.

E. V. APPLETON.

Halley Stewart Laboratory,
King's College,
London.
June 3.

[2] *J. Inst. Elec. Eng.*, 72, No. 435, 246; 1933.

[3] Pannekoek, *Amst. Acad. Proc.*, 29, 1165; 1926.

[4] Eckersley, *J. Inst. Elect. Eng.*, 71, No. 429, 423; 1932.

WE were much interested in the letter of Messrs. Schafer and Goodall in NATURE of June 3, p. 804, under the title "Characteristics of the Ionosphere", and in particular in their remarks about the presence of an ionospheric reflecting region between the *E* region and the *F* region of Appleton. While making automatic records of ionospheric reflections[1] we have recently found indications of this region on several occasions.

One of our records, for the morning of January 29, 1933, taken on a wave-length of 150 m., is reproduced in Fig. 1. On this occasion a "circularly polarised receiver"[2] was used, and was arranged so as to receive left- and right-handed circularly polarised waves alternately; a black line at the upper edge of the record corresponds to the reception of right-handed polarisation. At 0655 G.M.T., reflection of the right-handed component at the *F* region begins, at 0712 G.M.T. the left-handed component appears, at 0735 G.M.T. the right-handed component 'jumps' to the intermediate region at a height of 175 km. and at 0750 G.M.T. it disappears due to absorption. At 0835 G.M.T. the left-handed component 'jumps' to the intermediate region and a double reflection from the intermediate region is recorded. At 0930 G.M.T. a discontinuous 'jump' from the intermediate to the *E* region is seen, and for a few minutes reflections from the two regions occur simultaneously. A little later double reflections from the *E* region appear.

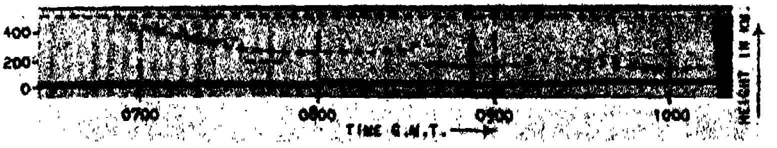

FIG. 1.

The sudden jumps from *F* to the intermediate region, and from the intermediate to the *E* region, indicate clearly that the three regions are distinct, while the fact that the jump from the *F* to the intermediate region takes place at different times for the right- and the left-handed components shows that the intermediate region is mainly composed of electrons.

The Hydroxyl Group and Soap Film Structure

IN view of the well-known 'stabilising' effect of glycerin on soap solutions, it is not surprising to find that the elastic recoil of aqueous ammonium oleate—demonstrated by Hatschek at a Royal Institution discourse in 1927[1]—is destroyed by a small addition of glycerin: the resulting solution having no obvious anomalous viscosity. (Hatschek supported a hollow glass cylinder on vertical pivots in a quarter per cent solution of ammonium oleate: when this cylinder was spun by the finger and thumb, it rotated for a few seconds, but then, after stopping, slowly returned in the opposite direction, as if by a coiled-up spring.)

Besides glycerin, many other alcohols, however, have an even more striking effect on aqueous ammonium oleate, sufficiently interesting to place on record. The mucilage-like consistency of 9 per cent ammonium oleate is changed by small additions of glycol, propylene alcohol, cyclohexanol, and ordinary ethyl alcohol, among other substances, first to a thick but perfectly clear gel, transforming in a short time, or on further small addition of the alcohol, to a limpid, free-flowing, normal, clear liquid. The actual amounts that produced this result, when added to 20 c.c. of 9 per cent aqueous ammonium oleate, were 4·5 c.c. glycerin, 2·8 c.c. glycol, 1·1 c.c. propylene alcohol, 0·5 c.c. cyclohexanol, and 1·2 c.c. ethyl alcohol. The resulting solutions, especially when diluted, give lasting thin films which have in most cases the interesting property of thinning to the 'black' state through several grades, so that ordinary photographs of three or four well-defined black grades can often be obtained present at the same time, though aggregating at different rates.

This reaction would also suggest that soap molecule aggregates are formed by means of hydroxyl groups rather than as ordinary hydrates; and seems to indicate a mechanism by which sheets of such molecules are rooted in a water surface, or linked in a stable soap film. In any event, the addition of alcohols as described here has evidently resolved some of the complications of the colloidal structure of the aqueous oleate.

Interaction between Soot Films and Oil

THE effect described by Mr. J. H. Coste in NATURE of May 13, p. 691, is a manipulation variation of the interaction reported by me in NATURE of March 12, 1932, p. 401, as a new observation.

The drop *falling* on the film, the result is a record of impact rather than the effect of an undisturbed interaction. The drop being carefully *posed*, the central dark zone, varying from 0·25 cm. to 0·5 cm. in diameter, is a beautiful self-contained ring system, of so small diametrical variation that microscopic examination is necessary. A minute clear-dot puncture circle—probably through faulty posing—sometimes occurs, like a planet on the zone centre with perhaps a dozen surrounding satellites. This puncture circle increases with increased distance of fall, and at 3 mm. is quite large, whilst at 3 cm.

the dark zone is completely split into the striking spectacular visible effect noticed by Mr. Coste. This is an impact effect, the beautiful microscopic ring system obtained by the orderly reaction when the drop is posed being totally destroyed. Excepting possible central punctures, there is continuity throughout the system, and no film displacement forming 'clots' of carbon if the drop be posed, but a pleasing gradation of visible light and dark zones without suggestion of strain. A striking visible pattern persists outside the central dark zone, revealing microscopically orientated strings of carbon particles (or agglomerates) of denser or rarer conformation, with gradient transition between rings.

The striking periodic motive throughout a diameter of 2–3 cm. when the drop is posed, contrasts with the destroyed periodicity in the dark zone—only irregularly propagated outside—produced by falling impact.

The viscosity, vapour pressure, manner of introduction, and 'setting' rate of drop material seem to decide overall diameter. If too viscous, the film is plucked away; if too mobile, too rapid spread with but transitory system formation occurs. High, but not too high, viscosity produces best results and, amongst many other substances tried, a brand of immersion oil, whilst the soot film should be neither too patchily thin nor obscuringly dense.

If Mr. Coste decides to try posing the drop, as first used, he will surely find enhanced beauty due to interaction but slightly impeded by impact, and the setting-up of well-marked periodicity.

Vitamin C in the Adrenal Gland

A NUMBER of attempts have been made to obtain cytological preparations of vitamin C in the adrenal, based upon the well-known reducing power of the vitamin (ascorbic acid)[1].

The solubility of vitamin C in water makes it impossible to use the customary fixatives. In this work fixation was therefore accomplished by suspending pieces of the gland in the vapour of formaldehyde, obtained by heating paraformaldehyde. The gland tissue fixes rapidly and well by this method.

The method of demonstration which gave the best results was the impregnation of the gland using silver nitrate[2]. This gave good, though erratic, results. Following fixation, the gland was placed in 2·75 per cent solution of silver nitrate for twenty-four hours. Further methods using alcoholic silver nitrate of various strengths gave varying results.

In the mouse adrenal the cortex first stained an intense black and after two or three hours the medulla also became black. Paraffin sections of the gland showed cortex and medullary cells to contain large numbers of very small brownish black granules. The usual tendency towards surface tension aggregation at membranes was present, with the result that the nucleus was practically obscured by the mass of granules surrounding it. The cytoplasm of the cell was bordered by aggregations of these granules, and a number were scattered through the cytoplasm itself. Fig. 1 illustrates the arrangement of the granules within the cell. The cortex exhibited this reaction in patches, but the medulla showed an even impregnation, without the tendency to aggregation at membranes that was present in the cortical cells.

In the adrenal gland of the cat the peripheral cortical cells (zona glomerulosa and outer zona fasiculata) tended to impregnate more strongly than the inner cortical cells and the medulla. This was not due to imperfect penetration as the gland was cut up into a number of transverse portions for impregnation.

Guinea-pig adrenals showed impregnation of both cortex and medulla.

In the adrenals of the animals used in this work a number of cortical cells were packed with globules (lipoidal ?) and the granules of vitamin C were aggregated around the edges of the globules, presumably due once more to surface tension action.

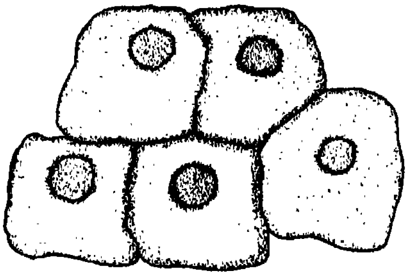

FIG. 1.

As a control, a number of pieces of adrenal gland were soaked in water for an hour, thus allowing the vitamin C to dissolve out. There were no black granules present in the material on subsequent examination.

Carbonic Anhydrase and the State of Carbon Dioxide in Blood

MANY physiologists hold that sodium bicarbonate is the main form in which carbon dioxide is carried in the blood, and that the elimination of the latter in the lungs is due to the reaction

$$\text{HP[representing the weak protein acids of the blood]} + \text{NaHCO}_3 \rightleftharpoons \text{NaP [protein salt]} + \text{H}_2\text{CO}_3 \qquad \text{(i)}$$

followed by

$$\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O} \qquad \text{(ii)}$$

Reaction (i) is very fast, but reaction (ii) is known to be slow. Calculations by Henriques[1] and others show indeed that (ii) is too slow to explain the observed rate of CO_2 escape in the expired air. Either then there must be a catalyst for reaction (ii) in the blood, or else some quite different chemical mechanism must operate.

The factor catalysing the $H_2CO_3 \rightleftharpoons CO_2 + H_2O$ *reaction.*

Following on the work of Hawkins and Van Slyke[2], and Brinkman and Margaria[3], we[4] isolated in 1932 from ox-blood, a white substance of which 1 in 10,000,000 is active. This extract is a typical enzyme, and since it seems to be distinct from other known enzymes, has been christened 'carbonic anhydrase'.

A second mechanism. Direct combination of CO_2 with proteins.

Such compounds (possibly of a carbamate type) have been suggested by Bohr, Buckmaster, Mellanby and lately Henriques. Their detection in normal blood is hindered by the presence of the carbonic anhydrase, but by poisoning the latter by addition of *M*/10 HCN we have found new and clear-cut evidence for their existence.

(*a*) If such cyanide blood (free of CO_2) is shaken with CO_2, there is first a rapid uptake followed by a long slow one. The latter is due to the reaction $CO_2 + H_2O \rightarrow H_2CO_3$ which in absence of catalyst proceeds slowly. In the rapid stage much more CO_2 is taken up than can be accounted for by mere physical solution. The excess must be due to a chemical combination, which is *not* bicarbonate.

(*b*) Ammonia, glycine and peptide solutions behave just like the cyanide-blood. The CO_2 uptake in the rapid stages is in all these cases much increased by alkalinity and by lowered temperature. For the simpler NH_2 containing compounds (ammonia, etc.) it is certain that the compound so formed is a carbamate, that is,

$$RNH_2 + CO_2 \rightarrow RNHCOOH$$

So it seems extremely probable that the same is true of the cyanide-blood also.

(*c*) At 0° C. and physiological *p*H, 10–20 vols. per cent CO_2 are taken up in this carbamate-like form by cyanide blood, when the gas phase contains 40–50 mm. CO_2 pressure.

(*d*) In reduced blood, the carbamate-like compound, at CO_2 pressures from 20–60 mm. mercury amounts to about 5 vols. per cent more (measured as c.c. CO_2) than in the case of oxygenated blood, thus suggesting that hæmoglobin is the chief blood protein concerned. At 15° C the difference is almost as large, but the absolute amounts are much less. Since controls suggest that the only effect of this cyanide is to poison the carbonic anhydrase, we must suppose that these carbamate-like compounds are also present in normal blood and hence are important both in experiments on blood at 15° C and below, and also in CO_2 transport by cold-blooded animals.

(*e*) At mammalian body temperature (37° C) the carbamate-like compounds must, owing to the temperature effect noted above, be much less in amount. Some, indeed, of the difference between those physiologists who have upheld the bicarbonate mechanism as the sole mode of CO_2 carriage, and those who have supported a direct combination of CO_2 with the blood proteins may be due to the former usually having worked at 37° C and the latter at 15° C or below. We are at present extending our work to 37° C so as to assess the rôle of carbamate-like compounds in mammalian CO_2 transport.

Finally we would emphasise again that the formation of these carbamate-like compounds is quite distinct from the bicarbonate mechanism and, unlike the latter, does not seem to be catalysed by carbonic anhydrase.

The Astronomical Radiative Stability

SIR JOSEPH LARMOR in his letter in NATURE of June 3 concludes that because the temperature of the earth's surface has never changed by 50° C. in excess or defect of its present value since the commencement of organic evolution—as that would have destroyed all organic life—the effective temperature of the solar radiating surface cannot have changed from its present mean value, 6,000° K., by 1,000° in excess or defect.

This conclusion is based on the erroneous assumption that the temperature of the earth's surface reacts to a change in solar radiation like a black body able to radiate into free space. The reality is entirely different, for the surface is surrounded by an atmosphere of water vapour which is extremely opaque to long-wave terrestrial radiation, and the temperature of the earth's surface plays only a subordinate part in the balance of incoming solar radiation and outgoing terrestrial radiation. I discussed the question of the balance of solar and terrestrial radiation in a paper published in 1928[1], taking into account the selective absorption of water vapour and the actual temperature existing in the earth's atmosphere.

One of the chief results of the investigation was to show that, if the solar radiation increased, there would be an initial rise of temperature, but that this would lead to an increase of cloud amount which would reflect the short-wave solar radiation, and the balance would be reached by increased reflection and not by increased temperature. I gave reasons to believe that the results of increasing or decreasing the solar radiation within very large limits would be mainly an increase or decrease of cloud, the temperature changes being relatively small. This conclusion was supported by a calculation which showed that if the solar radiation decreased to three-fifths of its present value, clouds would entirely disappear, while if it increased to twice its present value, the sky would be completely overcast. As it happens, Mars and Venus, both planets with water vapour in their atmospheres, are respectively at such a distance from the sun that they receive a half and double the amount of solar radiation received by the earth, and the former has no clouds and the latter is completely cloud covered.

The limits of solar variation discussed by Sir Joseph Larmor, ± 1,000°, are those which would correspond with halving and doubling the solar radiation: and would therefore be compensated by varying the amount of cloud from no clouds to overcast skies, with relatively small changes of temperature. Instead of Sir Joseph's conclusion that such variations of solar radiation have never taken place, there is good reason to believe that changes of solar radiation of this magnitude are of relatively recent occurrence. More and more evidence is being found that, during the Pleistocene period, there were several large variations of rainfall simultaneously all over the earth[2]. Evidence of two pluvial epochs and two dry epochs is found in most regions, and the advance and retreat of the ice, which were characteristics of this geological period, were secondary effects of the changing precipitation. The variation in the precipitation between a dry and a pluvial epoch was very great, much greater than is generally realised. The average rainfall during the pluvial epochs was probably four or five times the present rainfall, and as the precipitation extended over most of the present deserts, the sky was probably nearly overcast in all parts of the world. This could only have been brought about by a very large increase of solar radiation.

Origin of Tektites

DR. L. J. SPENCER'S contribution to NATURE of January 28, on the "Origin of Tektites", has interested me greatly, especially for the reason that his views tend to support that of the late Prof. J. W. Gregory and my own, as to the terrestrial origin of the australites. Dr. Spencer's explanation, however, does not appear to account for the occurrences and shapes of these australites, for the bomb-shaped ones have undoubtedly received their form by a spinning action, and not by a mere fusion of the sand covering the continental duricrust. Moreover, the australites are found in every State of Australia, and where they are abundant there is at present no evidence of meteoritic falls.

We may readily conceive how whirling dust in cyclonic storms, such as are known to take place in Australia, might be fused by the discharge of the lightning which often accompanies these electric storms.

The experiments of Prof. C. V. Boys on the discharge of electric sparks through molten resin tend to confirm this latter opinion, for he produced by this method many of the forms that are found in australites.

F. CHAPMAN.

National Museum,
Melbourne.
April 5.

MR. CHAPMAN'S theory of the origin of tektites, which is explained in detail in his book "Open-Air Studies in Australia" (1929), is one of the many contributions to this problem, and was mentioned in my article. But no tektites (aerial fulgurites) have been picked up after the discharge of lightning through dust-storms. On the other hand, bodies with a very close resemblance to tektites have been collected around the meteorite craters at Henbury in Central Australia and at Wabar in Arabia—at Henbury for a distance of a mile from the main crater. 'Bombs' of molten silica must have been ejected from the craters by the violent gaseous explosions, and spinning through the vapours they collected condensed silica with some iron and nickel on their surface. A test for nickel in australites will help to decide between the rival theories.

The "Leeds Portrait" of Joseph Priestley

SOME time ago, I came across a photographic copy of an early portrait of Joseph Priestley among the Canton papers in the library of the Royal Society.

According to H. C. Bolton in his "Scientific Correspondence of Joseph Priestley", the original portrait was at one time owned by Mrs. Bilbrough (née Ellen Priestley) and in 1787 it was taken by Mrs. Crouch (Priestley's sister) to Gildersome, near Leeds, where she lived as housekeeper to William Hudson, a local resident. It is this association with Leeds which has presumably caused it to be known as the "Leeds portrait". How long it remained at Gildersome is not known, but it was photographed in 1860 by Messrs. Caldesi, Blanford and Co., 13, Pall Mall East, London. Since that time, the original appears to have been lost sight of and no reproduction of the portrait has hitherto been published.

It is of particular interest in that it is the earliest known picture of Priestley, representing him at the age of thirty years (1763) as he appeared during the first part of his stay at Warrington. It was at this stage of his career that he was introduced to scientific circles in London during a Christmas holiday in 1765, when he made the acquaintance of John Canton and Benjamin Franklin, who were mainly responsible for his election as a fellow of the Royal Society in the following June. It was to them that he owed his first interest in original research, which he undertook in order to prepare the way for his "History and Present State of Electricity" published early in 1767. No other Priestley portrait dates from this important period of his life.

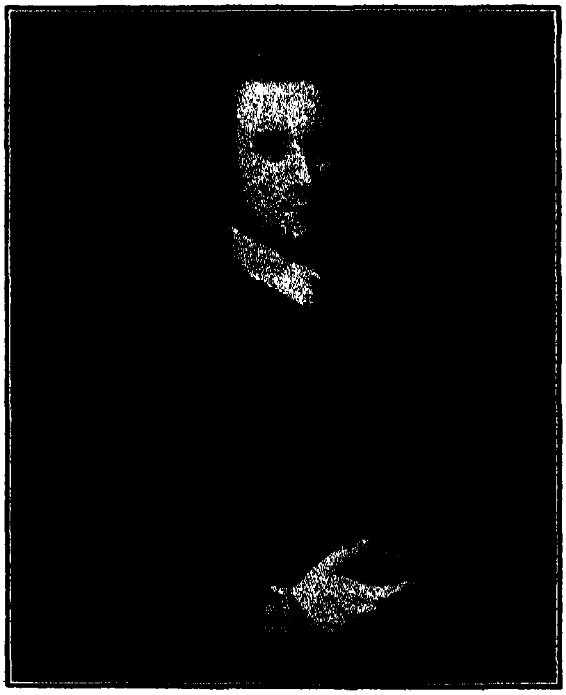

FIG. 1.

The Royal Society copy, from which the accompanying print (Fig. 1) has been reproduced with the permission of the Council of the Society, was evidently incorporated in the Canton collection by Dr. James Yates because of Priestley's friendship with Canton between 1765 and the latter's death in 1772. Two other Caldesi, Blanford prints are known to exist; one in the Timmins' Collection in the Reference Library, Birmingham; the other in the United States.

I shall be glad to hear of the existence of other copies of this photograph and I shall especially welcome any information which may lead to the finding of the original.

Crystal Structure and Orientation in Thin Films

IN crystal growth, the well-known phenomenon of pseudomorphism extends to all three dimensions. Recently we have found that thin films of aluminium on platinum, of zinc oxide on zinc and of magnesium oxide on magnesium possess abnormal crystal structures. For example, aluminium, normally of face-centred cubic structure ($a = 4·05$ A.), when deposited as a sufficiently thin layer on face-centred cubic platinum ($a = 3·91$ A.) acquired a face-centred tetragonal structure with basal axis 3·90 A. and major axis 4·02 A. Thus, in its basal dimensions the aluminium was pseudomorphic with the platinum substrate. A similar effect was observed in the case of a thin film of zinc oxide on zinc (triangular close-packed lattice, $a = 2·685 \pm 0·002$ A.; $c = 1·86$). In this case, whilst the basal dimensions of the zinc oxide were similar to those of the zinc substrate, the major axis had increased from 5·178 A. (normal zinc oxide) to 6·873 ± 0·002 A. Thus, the volume of the abnormal zinc oxide cell, basally pseudomorphic with normal zinc, was nearly equal to that of the normal zinc oxide cell.

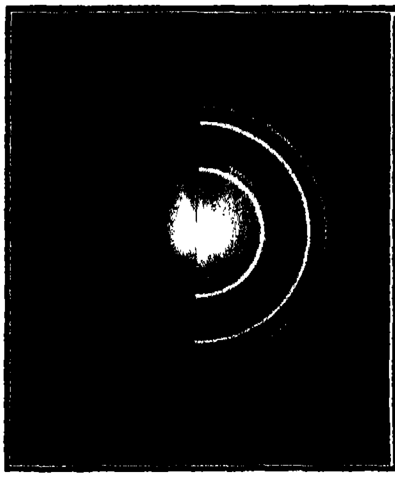

FIG. 1.

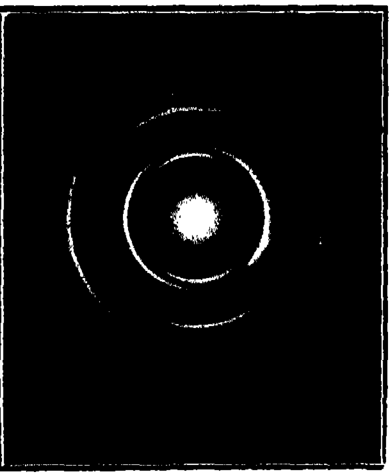

FIG. 2.

Owing to deep penetration, the intensity distribution between the rings of X-ray diffraction powder photographs is of great assistance in their analysis, because the ring intensities may be taken as being proportional to the atom densities of the corresponding planes. Hitherto it seems to have been generally supposed that this practice can be extended to electron diffraction analysis and that orientation must result in a splitting-up of the rings into arcs. Owing to the limited penetrating powers of electrons, however, it is quite conceivable that such a view might lead to serious errors in analysis. Consider, for example, a diffracting film consisting (to take the most symmetrical case) of cubic crystals orientated with two axes normal to the electron beam, the crystal array being otherwise completely random. Rings due to (x, y, z) planes, where x, y and z are integers, will be missing from the pattern, which will consist solely of rings due to planes parallel to the beam axis, that is $(x, y, 0)$, $(0, y, 0)$ and $(x, 0, 0)$ planes. With gradual departure from this ideal case, diffraction will also occur from (x, y, z) planes, where z is large compared with x and y, but the intensity distribution between the rings will remain abnormal until all trace of orientation has disappeared. That such cases of orientation can and do occur may be illustrated by the following results:—

The electron diffraction pattern, *A* (Fig. 1), was obtained by transmission through a thin film of partially oxidised zinc. The reference pattern[1], *B*, was due to normal zinc oxide ($a = 3·220$ A.; $c = 1·608$) with random disposition of the crystals. Analysis of *A*, based solely on ring diameters, showed that the specimen consisted of normal zinc oxide together with small amounts of normal zinc ($a = 2·685 \pm 0·002$ A.; $c = 1·86$) and basally pseudomorphic zinc oxide ($a = 2·686 \pm 0·002$ A.; $c = 2·56$). On comparison of *A* with the reference pattern it will be seen that many normal zinc oxide rings are either absent or much weakened, whilst others are greatly intensified. For example, rings due to planes parallel to the basal planes of the hexagonal crystals are missing, whereas those produced by the $(x, y, 0)$ planes are abnormally strong. These facts show that the normal zinc oxide crystals in the specimen were orientated in such a manner that their bases were normal, or nearly so, to the electron beam axis, the directions of the basal axes, however, being completely random.

The pattern (Fig. 2) was obtained from a similar film which had been stretched. Whilst the composition of the film (normal zinc oxide, zinc and pseudomorphic zinc oxide) remained unchanged, the distribution of intensities between the rings is now entirely different, and the rings tend to break up into arcs. Comparison of the relative ring intensities with those of the reference pattern, *B* (Fig. 1), shows that, whilst some of the crystals were orientated as in the previous case, others were now disposed in such a manner that two rectangular faces of each crystal were normal to the beam axis. Moreover, the tendency of the rings to break up into arcs shows that the major axes of these crystals were orientated about the direction of stretch of the film.

'Bull-Dog' Calf in African Cattle

THE achondroplasia-like condition which gives rise to the 'bull-dog' calf is not uncommon in certain breeds of cattle, notably in the Dexter, in which it has been shown to have a definite genetic basis and to be due, possibly, to a retardation in the functioning of the pituitary during fœtal life (Crew[1]). In the Norwegian Telemark breed, Wriedt[2] has described a very similar condition which, however, is different genetically. It has also been reported in the case of the sheep (Crew and Roberts[3]).

The purpose of this note is to record the fact that the 'bull-dog' calf occurs in cattle indigenous to Africa. The first case came to my notice in April 1929 and occurred on one of the few farms in Uganda owned by Europeans. Since then no fewer than twelve other monsters have been born, all of which presented the same characteristic abnormalities which justify the appellation 'bull-dog'. The specimens examined by me were quite typical of the condition as described by Crew, and every one of them occurred in Nganda cattle which are of a definitely fixed type and, so far as I can ascertain, breed true. They are supposed to have originated from a cross between the Ankole and the Eastern Province cattle. The Ankole cattle are characterised by their enormous horns, up to 6 ft. in span, leggy stature, and by the absence of hump, whilst the Eastern Province animals are typical zebus of small size. The Nganda cattle have medium-sized horns and a small hump. Buganda, the area in which these Nganda cattle are to be found, lies between Ankole on the western side and the Eastern Province to the east of the Nile. Although the owner of the farm on which these 'bull-dogs' occurred had cattle of all three types (Ankole, Eastern Province and Nganda) it was only the latter breed which produced them. Of the twelve which have been born since 1929, all save one were first calves. One of them was born alive but was killed after a few hours.

The Bahima, the pastoral tribe of the Ankole district in the west of Uganda, are employed as herdsmen, and unquestionably it is known to them that such 'bull-dog' calves are not uncommon. But it is impossible to obtain any information as to their incidence in the tribal herds for the reason that the monster is regarded as an omen of bad luck to the herd and to its owners. Some of the herdsmen would not even look at the 'bull-dog' calf, and the opinion prevails that if a woman of the tribe sets eyes on it she is bound to become bewitched and to produce a similar abnormality herself. So it is that, though the 'bull-dog' calf is probably fairly common among the cattle of the Western and Buganda Provinces, one hears nothing of them. They are got rid of quickly and never mentioned. This is the reason why the 'bull-dog' calf is never encountered in herds owned by natives: it was only because these cattle were owned by Europeans that I am able to record their occurrence in Nganda cattle.

Distribution of Nitrates in the Soil and Root Development in Coffee

IN the course of some preliminary investigations, after rains, upon the distribution of nitrates in the lower levels of a Kikuyu lateritic red loam, upon which coffee was growing, it was found that the curve showing distribution with depth was always of the form shown in Fig. 1. As the surface soil dried with drought, the nitrate content decreased, in some cases to so little as five parts per million, but the general shape of the curve remained the same, rising, generally, to a level of about forty parts per million, samples being taken at every foot to a depth of 8-12 ft.

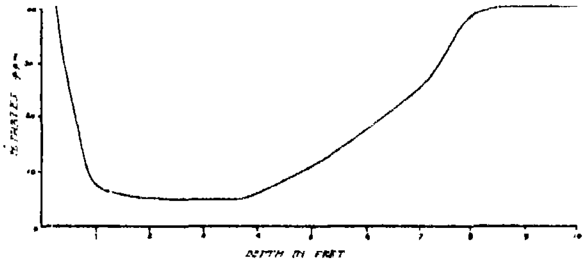

FIG. 1.

Comparing the curves of nitrate distribution with graphs of root distribution, it appears that the zone of low nitrate concentration coincides with the zone of vigorous development of root growth, that is, the coffee bush does obtain a substantial part of its nitrogen requirements from the lower levels of the soil. This investigation is being extended, but in the meanwhile it would be interesting to learn if any similar observations have been made in connexion with other fruit trees or crops. No references can be found in our limited library.

Neutron, Proton and Positron

THE neutron is usually looked upon as an aggregate of a proton and an electron. If it were so, there ought to be a strong tendency for hydrogen atoms to be converted spontaneously into neutrons, and the number of neutrons present in the universe should be much higher than it is assumed to be. I suggest that *the proton be considered as an aggregate of a neutron and a positron*. The neutron would be looked upon as an elementary material corpuscle without electric charges altogether. The proton would be able to dissociate into a neutron and a positron.

The very small number of neutrons and positrons met with in the universe would then be easily explained by the fact that the dissociation of protons requires a large quantity of energy and is by no means spontaneous.

Research Items

'Diffusion' and Disease. An argument in favour of Dr. Paul Rivet's theory of the Oceanic origin of certain of the Indian peoples of America has recently been deduced from the character and distribution of typhus by Dr. Charles Nicolle (*J. Soc. Américanistes*, S. 2, 24, fasc. 3). Two distinct forms of typhus are now recognised. The older and classical form is found in man only, is carried by lice and has a distribution which is confined to the Old World, where it extends from Europe, through North Africa (but is not found in the tropical area) to western and central Asia and China. Although rats can be inoculated they are found not to be carriers, and are free from the virus after they have recovered from the fever. The second form has been identified as a disease of the rat, which is communicable to man, and is endemic in America. Its distribution, though not yet exactly determined, seems to be confined to America and the coastal parts of eastern Asia—Malaysia—Australia and New Zealand. It may be that eventually it will be found to embrace all parts. This form of typhus could not have been introduced into America by the Norsemen, as the carrier, the grey rat, was not then known west of the Urals; yet the disease was prevalent in America before the Spanish conquest, as is recorded by the chroniclers. As the rat could scarcely have accompanied the original migrations of the Indians over the inhospitable northern lands and also typhus does not occur in Alaska, one route alone remains, namely, that from Oceania, the rats having been carried on the canoes of the immigrants. There is evidently need of inquiry into the types of rats and of their parasites in Polynesia.

Prehistory of South-East Asia. An account of the search for evidence of prehistoric man in Siam, and of certain conclusions to be drawn therefrom, is given by Dr. Fritz Sarasin in *L'Anthropologie*, 43, Nos. 1–2. Siam, in contrast to Indo-China and Malaya, has furnished little evidence of prehistoric man, owing in part to the fact that the country is thickly covered with virgin forest, in part to the occupation of the caves, in which such evidence might be sought, by Buddhist shrines or by hermits. A number of caves were inspected in both the northern and southern extremities of the chain of low hills which traverses the country. Several of them, where the paving usual in such shrines did not cover the whole floor, yielded a number of implements of palæolithic type; and in one secondary cave trenches were dug. Here bed rock was reached at a depth of 1·6 m., through 20 cm. of sand, 80 cm. of loamy soil, tinted grey by ash, and containing pottery and crude implements of palæolithic type, round hammer-stones, fragments of red ochre and broken bones, and below these yellow earth with no traces of human occupation. Comparison of the material obtained with evidence from Indo-China and Malaya leads to the conclusion that in the archæology of south-east Asia it is possible to distinguish: (1) a palæolithic culture of a simple and very primitive type without any indication of polished implements, represented in the archaic Hoabinhian of Tonkin, the Siamian of Siam, and the Malayan Linggong culture, its age, probably, being miolithic (Menghin); (2) a debased palæolithic with isolated proto-neoliths in juxtaposition and no pottery, represented in middle Hoabinhian, the older Bacsonian of Kéo-Phay, and the lower deposits of Gua Kerbau in Perak, of later age than (1); (3) a culture which is still palæolithic in its principal characters, but with an increased number of polished implements and greater refinement in form, pottery appearing; represented in upper Hoabinhian and Bacsonian and the upper deposits of Gua Kirbau, its age epimiolithic (Menghin); (4) full neolithic. The palæolithic of south-east Asia is certainly post-glacial and, therefore, relatively recent.

Relationships of the Mammals of Vancouver Island. E. Raymond Hall lists twenty kinds of mammals from Vancouver Island, British Columbia (Univ. California Pub. Zool., 38, 1932, p. 415). Four are new subspecies, including a Vancouver Island wolf (*Canis occidentalis crassodon*), and the brown rat has been introduced. Comparison of this mammalian fauna with the faunas of the mainland and Alaska shows that, structurally, nine of the kinds have their closest relatives on the mainland of southern British Columbia, while six others more resemble forms which occur in south-eastern Alaska. On the whole, the insular fauna seems to have almost equal affinity with Alaska and with the proximal mainland in British Columbia.

Gorgonacea from the Great Barrier Reef. Prof. Sydney J. Hickson, in reporting on the Gorgonacea from the Great Barrier Reef Expedition 1928–29 (*Sci. Rep.*, 4, No. 13, 1932. British Museum (Natural History)) is in agreement with the naturalists of the expedition that gorgonids are rare on the Barrier Reef. In one locality investigated, however, he finds these corals are richly represented. This is the Penguin Channel lying between Snapper Island and the mainland, a short and narrow channel about one mile north-west of Low Island and about 13–14 fathoms deep, where no less than 42 specimens, belonging to 19 genera and 15 species, were obtained. The conditions in this channel are peculiar, with a flow of water in one direction over a rocky bottom and apparently very favourable to the growth of the Gorgonacea. This is entirely different from Panama Bay, where Prof. Hickson (1928) described the Gorgonacea as flourishing in an open and very muddy sea. There are no species common to the two regions although certain forms of ramification occur in both. The enormous variability of many species has not been sufficiently recognised and the spicules are found to vary so much in some genera that it is not safe to use them as specific characters. Careful examination of a number of specimens shows that many so-called species are really only local varieties of a much smaller number. The general forms of the ramifications are regarded as good characters for systematic determinations. The author also considers that colour may be of much value in systematic work, the pigment which colours the spicules being either present or absent. The species without any colour in any of the spicules are apparently distinct from those with colour in some or all of the spicules. From the few observations on the gonads the facts seem to indicate that most are in approximately the same stage in February and spawned later, perhaps in June and July.

Disposal of Debris by Blood-Vessels. Science Service reports that, at the meeting in Cincinnati, on April 12–13, of the Federation of American Societies for Experimental Biology, Drs. E. R. Clark and E. L. Clark of the University of Philadelphia reported further observations on the thin layer of tissue in a rabbit's ear which they have examined microscopically through two thin transparent windows. Their recent work has been directed to the solution of the problem as to how the body disposes of debris cast out of the blood-vessels. Lymphatic tissue, which has been credited with this scavenging, appears to be much less important in this respect than was previously thought, for in spite of the absence of lymphatic tissue or vessels in the area between the two windows, and with no outlet except by way of the small blood vessels, a central mass of blood cells, fibrin and blood plasma clears up rapidly and the debris disappears. The space it occupied becomes filled with small blood vessels and connective tissue. Some of the mass may be taken up by macrophages but most of it is disposed of otherwise. Whether it is first digested by enzymes or in some other way is transformed so that it can be absorbed by the blood is not known, but observations through the windows showed that it can leave the tissues in the window-chamber only by way of the small blood vessels, there being no lymphatic vessels to carry it away. Drs. Clark and Williams observed in the same tissue that the nerves controlling the contraction of the muscle cells of the arterioles may undergo new growth and may re-establish their control over the contraction of the blood vessels. Dr. Clark said that this appeared to be the first study which correlates the surface regeneration of the sympathetic nerve with the functional activity of the part of the body it supplies.

Effect of Weed-Killers on the Soil. A question of importance in the use of chemicals for weed eradication is the possibility of such compounds exerting a deleterious effect on the soil, with risk of injury to the subsequent crop. Some investigations on these lines have been carried out by W. E. Bowser and J. D. Newton both in the field, greenhouse and under controlled conditions (*Canadian J. Research*, 8, 73). The liability of damage depends in part at least on the rate of decomposition of the chemical, its rate of movement in the soil and its effect on microbiological activity. Sulphuric acid and copper sulphate, which are employed chiefly as leaf sprays for the suppression of annual weeds, showed no lethal effect on the soil and nitrification was not affected. Sodium chlorate, on the other hand, which is mainly used for the eradication of perennials, remained undecomposed for a considerable time, poisonous effects being found nearly two years after application had been made. The rate of decomposition, however, was accelerated in the presence of much organic matter, and further, leaching removed the toxic compound from the surface layers of the soil, facts which suggest that a shallow rooted crop supplied with a good dressing of an organic manure would be advisable after a sodium chlorate treatment. Sodium bichromate decomposed rapidly, showing no residual toxic effects, but both this compound and sodium chlorate were alike in exerting a depressing influence on the numbers of soil micro-organisms.

The Genus *Diaporthe*, Nits. A very complete account of the ascomycetous fungi comprising the genus *Diaporthe* appears in vol. 17, part 4, of the *Transactions of the British Mycological Society* ("The British Species of the Genus *Diaporthe*, Nits and its Segregates" by L. E. Wehmeyer, pp. 237–295, March 1933). A brief key to the segregated genera is followed by very extensive keys to the British species of *Diaporthe* proper and of *Cryptodiaporthe*. Each species is afterwards described in great detail. The single species of *Apioporthe* and the two of *Diaporthopsis* receive full treatment. The publication of this account is all the more welcome since several species of the genus under review often attack the same host plant, causing great difficulty of determination in the absence of specialised knowledge.

An Electrical Calculating Machine. R. M. Mallock has described (*Proc. Roy. Soc.*, May) an electrical machine for finding the roots of a set of linear simultaneous equations. The machine consists of a number of transformers, one for each unknown and one for the numerical constants. Each transformer bears several windings. The number of turns in a winding may be varied by a dial switch, and the number of turns are made proportional to the coefficients in the equation. The windings are connected in series circuits corresponding to the equations. If now one of the transformers is excited, the fluxes in the cores adjust themselves to make the total voltage in each equation circuit zero, and the fluxes are then proportional to the roots of the equations. Errors are produced by magnetic leakage and by the resistance of the coils, and the latter are reduced by supplying magnetising current to each transformer from a valve amplifier and thus reducing the current necessary in the equation circuits. The machine which has been constructed will solve ten simultaneous equations with errors in the roots which may be less than 0·1 per cent of the largest root. If the number of unknowns is less than the number of equations, the machine may be used to obtain directly the 'least square' value of the roots, the weights of the equations being introduced as resistances in the equation circuits. The machine may save much labour in physical and engineering problems.

Absorption of Penetrating Radiation. Prof. E. Regener holds both the height record and the depth record for measurements of the ionisation due to penetrating radiation. In a recent paper (*Phys. Z.*, 8, 306; 1933) he describes both how he made measurements in Lake Constance down to a depth of 230 metres below the surface, and how he sent up an ionisation chamber attached to a free balloon to a height of 25 km., corresponding to an atmospheric pressure of 22 mm. of mercury. The design of the self-recording instruments is described in some detail. In order to avoid the disturbing effect on the sensitivity of the electroscope of the very low temperature of the atmosphere at such great height, use was made of the principle of the forcing-house. The ionisation chamber was completely surrounded by a light cage, the top half of which was covered with cellophane and the bottom half with aluminium foil. This proved very effective, for the temperature of the apparatus itself actually rose to 35° C. at a height of 20 km. The absorption curve obtained from these measurements in water and in the atmosphere is analysed into five homogeneous components of radiation, with absorption coefficients of $0{\cdot}205 \times 10^{-3}$, $0{\cdot}735 \times 10^{-3}$, $2{\cdot}0 \times 10^{-3}$, $4{\cdot}1 \times 10^{-3}$ and $8{\cdot}5 \times 10^{-3}$ cm.$^{-1}$ of water. The contribution of the first three components to the ionisation at the top of the atmosphere is estimated as 0·16, 1·2, 3·2, and of the last two together as 328 ion pairs per c.c. per second. On the assumption that these absorption coefficients refer to homogeneous electro-magnetic radiation, Prof. Regener estimates the wave-lengths of the two harder components to be $3{\cdot}28 \times 10^{-14}$ cm. and $13{\cdot}7 \times 10^{-14}$ cm., by assuming the validity of the Klein-Nishina formula when the nuclear electrons are also taken into account. These wave-lengths are in close agreement with those of light quanta having energies equivalent to the masses of α-particles and protons. The possible mechanism of annihilation processes which could give rise to such quanta is discussed. The softest of the five components is attributed, following Millikan, to the building-up of a helium nucleus out of protons and electrons. The total energy of the penetrating radiation which falls on the top of the earth's atmosphere is estimated as $3{\cdot}5 \times 10^{-3}$ ergs per sq. cm. per second; this is 30 per cent lower than the erroneous figure given in Prof. Regener's letter in NATURE of January 28, 1933, p. 130.

Lead from Cyrtolite. The mineral cyrtolite from Brunswick, New York, contains lead and uranium in the ratio 0·0513 and is nearly, if not quite, free from thorium. The atomic weight of the lead extracted from this cyrtolite has been determined by Baxter and Alter (*J. Amer. Chem. Soc.*, April). The lead was converted into chloride after exhaustive purification and the comparison with silver effected nephelometrically, the end point being approached from both sides. The estimated accuracy is 0·02 in the atomic weight of lead, which was found to be 205·924, that of common lead being 207·211 and that of lead from Swedish kolm, previously investigated by Baxter and Bliss, who found 206·013, being 206·007. Cyrtolite lead is essentially free from common lead, so that the lead-uranium ratio may confidently be employed in calculating the age of the mineral. The explanation of the low atomic weight is not obvious. Aston finds the lead isotopes integral with the mercury isotopes, which on the physical scale $O^{16} = 16{\cdot}0000$ had values 0·01 per cent higher than integral, the accuracy claimed being 0·01 per cent. If the conversion factor 1·00022 to the chemical scale $O = 16{\cdot}0000$ is used, the atomic weight of radium lead falls between 205·96 and 206·00. However, if the latter is always accompanied by actinium lead, Pb^{207}, in the proportions found in Katanga lead by Aston (NATURE, 129, 649, April 30, 1932) the average atomic weight of uranium lead should be 0·07 unit higher, a difference which Baxter and Alter say is far outside the apparent accuracy of their experiments. This suggests the possible presence in uranium lead of isotopes of mass below 206. Alternative explanations are that the atomic weight found by Baxter and Alter is too low or that the packing fraction of lead found by the mass-spectrograph is incorrect.

Astronomical Topics

The New Planet, 1933 HH. Further calculations have been made on the orbit of this planet by Dr. A. Kahrstedt of the Berlin Rechen-Institut. He uses photographic positions obtained at Johannesburg, extending from April 22 until May 17; but even this interval of 25 days proves to be insufficient to permit of an exact determination. He gives the two following orbits, both of which satisfy the observations within a few seconds of arc; the epoch for both is 1933 May 8.0, and the equinox 1933.0.

	First Orbit	Second Orbit
M	225·0638°	259·0403°
ω	130·3251	98·5149
Ω	340·0096	341·1686
i	7·2154	7·1040
φ	10·6735	8·1309
n	1859·510″	1550·297″
log a	0·187072	0·239728
Period	1·90813 y.	2·28871 y.

Both orbits indicate that the planet will be an easy telescopic object during the autumn. According to the first orbit it would approach the earth within some thirty million miles in December, and might be faintly visible to the naked eye; the second orbit would place it about twice as far away. In either case it would rank amongst the brightest of the minor planets, and its tardy discovery is somewhat of a mystery. It was badly placed at first for northern observers, but it is now observable as a morning star shortly before dawn. The following ephemeris is for 0^h.

	R.A.	N.Decl.	Mag.
June 17	$0^h\ 49^m\ 31^s$	5° 8′	9·3
25	1 5 7	7 13	
July 3	1 20 37	9 17	
11	1 36 1	11 20	
19	1 51 20	13 23	8·7

Eclipse of Hi and Ho. The story of these two ancient Chinese officials who were executed for some failure of duty in connexion with an eclipse of the sun is briefly mentioned in many books of descriptive astronomy. Dr. J. K. Fotheringham, in the April number of the *B.A.A. Journal*, gives the results of a careful study of all the documents that throw any light on the matter.

There was a great destruction of documents in China in 212 B.C. by order of the reigning Emperor; many of these were afterwards rewritten from memory, though no indication is given of the degree to which the restored texts can be trusted to be in agreement with the original. Dr. Fotheringham states that at the epoch referred to (about 2000 B.C.), it was not possible to predict eclipses, but the mean length of the lunation was known, and the calendar, which was a lunar one, was regulated accordingly. The fault of the officials was not the failure to predict an eclipse, but the fact that they allowed the calendar to get into confusion, so that an eclipse of the sun was observed on a day that was not the first of the month by their reckoning. This failure is stated in the narrative to have merited death, but their execution is not actually recorded.

Dr. Fotheringham does not think that it is possible to fix the exact date of the eclipse. He says that the one of 2155 B.C., which is selected by some writers, was not visible in China. The only clue is the statement that the eclipsed sun was in Fang. This is the name of an asterism in the head of Scorpio; but the word Fang is also used for "The order of the constellations", in which case it gives no assistance in finding the date.

The article also describes the musical and other ceremonials, including offerings of silk, that were customary at the times of eclipses.

The Royal Observatory, Greenwich

ANNUAL VISITATION

THE annual meeting of the Board of Visitors of the Royal Observatory was held on June 3. The Astronomer Royal, Dr. H. Spencer Jones, presented his report, noting that most of the work described in it had been carried out under the direction of his predecessor. The building and dome of the new 36-inch Yapp reflecting telescope have been completed; the telescope is being made by Sir Howard Grubb, Parsons and Co.; the spectrograph by Messrs. Adam Hilger, Ltd. Both have reached an advanced stage. Considerable progress has been made with the new transit circle which is being made by Messrs. Cooke, Troughton and Simms, Ltd.

Commander Gould has completed the restoration of Harrison's Time Machine No. 1, which is now in going order. He has also made a set of drawings of all parts, indicating those that replace original parts. He notes that Messrs. T. and F. Mercer generously supplied the balance springs and other new parts.

Meridian observations of the moon were made on 91 days. The mean correction to the longitude given by Brown's tables was +4·6″; it has been steadily diminishing since 1923, when it was +7·2″.

The second star catalogue for the epoch 1925 is in the hands of the printers; it contains all the stars, 10,600 in number, between north declination 32° and 64°, down to magnitude 8·0, also fundamental stars outside these limits. The proper motions of all the stars have been determined. The region from the equator to declination 24° is now being observed; this will be the last fundamental programme with the present transit circle. It is noted that, since its erection in 1851, about 600,000 star transits have been observed with it; also that, on the completion of the present catalogue, all the stars in the northern hemisphere down to magnitude 7·5 (and very many fainter ones) will have been observed at Greenwich since 1897. Vol. 6 of the Astrographic Catalogue was published during the year; it completes the determination of proper motions of stars in the zone between declination 64° and the pole; there are 252 stars that have proper motions exceeding 20″ per century.

The parallaxes of forty stars were published during the year, deduced from photographs taken with the Thompson equatorial; it brings the total number of parallaxes determined at Greenwich to 500.

The study of colour-temperatures of stars is being continued; a volume containing results for 63 stars was published during the year.

Good progress is being made with the measurement of plates taken for the determination of the parallax of Eros at the apparition of 1931. A new micrometer by Hilger, with a long screw, has been purchased.

Sunspot activity diminished further during the year; there were, however, two spot groups of considerable size; the largest one crossed the central meridian on Feb. 7. Observations of hydrogen flocculi with the spectrohelioscope were made daily when possible; the largest radial velocity measured was 110 km./sec. outwards on Oct. 6.

The usual magnetic observations were made at Abinger. The mean elements for 1932 were:—Decl. 12° 2·6′ W.; Hor. Force 0·18536; Vert. Force 0·42940; Dip 66° 39·1′.

The mean temperature for the year was 50·5°, being 1·0° above the average; the extremes were 98·9° on August 19 and 20·0° on Jan. 23. The rainfall was 24·77 inches, being 0·53 above the average.

Dr. J. Jackson resigned on March 1 his appointment as chief assistant, having been appointed His Majesty's Astronomer at the Cape. He had held his appointment since 1914, and has taken part in three expeditions to observe total eclipses of the sun.

Falling Water-Level in the Chalk under London

A DISCUSSION on the "Falling Water-Level in the Chalk under London" was held by the Geological Society of London on May 19. In opening the discussion, Mr. Dewey said that London's subterranean water supply, derived from the Chalk, is maintained by rainfall. When artesian wells were first sunk, pressure was sufficient to raise water through the Tertiary beds to above sea-level. To-day, the water-table of the Chalk waters has sunk over wide areas to a depth of 200 ft. below Ordnance datum. This fall has been brought about by two possible main causes: first, the withdrawal of large quantities of water through numerous wells and boreholes sunk by water companies and others to the Chalk in the central area and in the Chalk along its outcrop south and north of the Tertiary beds; and secondly, the diversion of water, in drainage and other works, from the Chalk to sewage farms on the Tertiary beds and its consequent loss to the reservoir. A third, and only a minor source of loss, is the water pumped from the Chalk to supply districts lying on beds below the Chalk. As a result of these abstractions the water-table has fallen continuously for the last sixty years at least. In 1878, the water-table under the City lay at 100 ft. below Ordnance datum: to-day it is at about 210 ft., equal to a fall of 100 ft. in fifty-five years. The rate of fall is accelerative, and during recent years can scarcely have been less than 3 ft. annually. There appears, therefore, to be a grave prospect of the failure of some wells in the central area.

Schemes for the maintenance of the water-level have been suggested, but the risk of pollution has to be carefully considered before they are adopted.

Mr. J. Romanes said that the principal question is whether underground water supplies and underground storage are being used to the best possible advantage. Although no water engineer would think of constructing a surface reservoir until he was satisfied as to the intake, large sums of money have been expended in obtaining water from subsoil sources without any serious thought being given to the question of adequate replenishment. Nature, lavish in the provision of underground storage, is much less generous in replenishment, and the whole trend of the modern development of land drainage and similar services is to curtail still further natural replenishment.

The dangers Mr. Romanes foresees from a continuance of the present conditions are: a failure of the water supply from private wells, involving costly schemes to replace this supply from outside the London area; the spread of contamination in the basin due to the admission of polluted or brackish water; and subsidence due to the removal of an upward hydrostatic pressure on the base of the clay series of something like 3 tons per square foot, or a total upward pressure of more than 90,000,000 tons under the 'City square mile', together with the drying out of the Tertiary gravel beds.

The possibility of artificially aiding replenishment by the introduction of surplus water from the Thames and its tributaries is well worth serious investigation.

Dr. Herbert Lapworth's contribution showed that no general lowering of the water-level has been traced north of the line Bushey–Potters Bar–Hoddesdon, and it is not likely ever to occur north of this line in Hertfordshire. It appears from maps showing lines of equal lowering at 25-ft. intervals that the limiting line of 'no lowering' coincides with places where the underground water-level of the Chalk enters the Lower Tertiary gravel and sand bands between Bushey and Hoddesdon. This fact, which has never before been demonstrated, suggests that the Tertiary sands and gravels at the top of the Chalk are the main 'carriers' or 'replenishers' of London's underground water supply. These Tertiary beds between Bushey and Hoddesdon receive water from the Chalk at a certain rate dependent on the carrying capacity of the Chalk. They can convey water at a more rapid rate if the hydraulic gradient were steepened, but the supply is limited by the amount delivered from the Chalk. North of the Bushey–Hoddesdon line there has been no lowering of the water-level since 1878, and pumping to the south of the line only steepens the gradient of the water-table but does not draw faster into the reservoir.

Mr. E. Batchelor said that experiments by Mr. F. H. King on percolation through a black marsh soil indicate that percolation through the London Clay into the Thanet Sands below is not inappreciable. The percolation through the Chalk since it was raised above the sea has, by dissolving the Chalk, opened many fissures. One inch of percolation through the Chalk not covered by Eocene strata within the basin of the Thames above a point just down-stream of its confluence with the Lea would, if intercepted, yield 60,000,000 gallons of water a day.

The level of the water in a well is individual to that well, and varies with the yield and depth of each well. These levels should, therefore, be shown on a diagram by a series of dots and not by continuous contour-lines. The density of wells to each square mile is much greater in the City of London than elsewhere. The yield of the wells in 1913 was about 3,500,000 gallons a day. It would be greater if the wells were deepened, and still greater if more wells were sunk.

Prof. W. B. R. King commented on the complex nature of the problem. There are three main types of water-bearing rocks to be considered: (*a*) the Chalk where the joints and cracks had been opened by freely circulating rain-water; (*b*) the Chalk under the Tertiary beds and where the cracks had not been opened by circulating water; and (*c*) the Thanet Sands. It is difficult to decide in the London Basin exactly how the water travels to the centre of the area. In the north of France, however, the Thanet Sands are separated from the Chalk by an impermeable clay, and certain bores about six miles from the Chalk outcrop afford evidence that in that region more water travels in the sands than in the cracks and joints of the Chalk.

Association of Teachers in Technical Institutions

THE twenty-fourth annual conference of the Association of Teachers in Technical Institutions was held at Lincoln during the Whitsuntide vacation. A civic welcome was accorded to the Association by the Right Worshipful the Mayor of Lincoln, who was accompanied by the chairman of the Education Committee (Councillor Mrs. Lane) and the Very Rev. the Dean of Lincoln. The president for 1933–34, Mr. F. H. Reid, was inducted by the retiring president, Mr. S. H. Moorfield.

In his presidential address, Mr. Reid covered a wide field. If technical education is to play its part, he said, technical teachers must realise still more that their work touches all points of the social, educational and industrial fields. They have to deal with problems of unemployment for which science and technology will be increasingly responsible, with the problem of equalising the efficiency of distribution and production, with the problems raised by continental countries which are using technical education as a weapon in international competition, with the whole vast problem of preparing students to take their place in a world changing with marvellous rapidity.

Admitting that many of these points were familiar to the audience he was addressing, Mr. Reid insisted that their implications and significance are not yet generally grasped. How else could a London evening newspaper make the following comment: "The machine is enslaving us. The technical sciences are its janissaries. Liberal education is the last stronghold of the free. Beleaguered and starved, its overthrow is only a matter of time." The news which prompted that comment, remarked Mr. Reid, came from the Continent by telegraph or telephone. It was doubtless sent to the room where the article was written by similarly swift and sure methods. The room was almost certainly lit by electric light. The writer was clothed in garments made by modern scientific processes. Just as marvellous processes transformed his thoughts into the printed word. Complex transport arrangements brought the newspaper to its readers in the space of minutes, while the writer doubtless went home by tube, and, warmed and comforted by smokeless fires, gave himself up to the enjoyment of music broadcast by means of the latest "technical sciences". Yet he is enslaved by the machine! How long will it be, asked Mr. Reid, before there is a general realisation that the ordered, efficient State towards which all technical sciences work is the only structure in which beauty and freedom can ultimately really be known?

Among the resolutions adopted by the Conference was one urging that extension of technical education with a minimum of duplication of effort, can be effected only by some system of consultation and co-operative planning within larger administrative areas than are in existence at present. It was insisted, however, that in arranging such regional co-ordination, teachers should be brought into consultation. Another resolution urged that apprenticeship conditions (or their equivalent) should be restated for the various industries and that the whole question of conditions of entry into industry and of the provision of opportunity for young entrants to qualify for skilled operative and higher posts should be immediately considered.

Food of Icelandic Herrings*

DR. P. JESPERSEN has made an important contribution to the biology of the herring in his investigations on its food in Icelandic waters. A large number of adult fishes have been examined, mostly collected during the great herring fishery of Iceland from June until September. The nets used were the purse-seine, fishing chiefly in the surface layers near the coast, and the drift-net, fishing in the deeper water of the open sea.

The food was found to be very different in the herrings from the two nets even if they were caught in the same water, those from the seine net having far more food in them—not one being found without food—while those from the drift-net were often empty, especially in autumn. This is presumably explained by the fact that the surface waters fished by the purse-seine nets have far more food in them in the summer than the deeper waters fished by the drift nets. The stomachs with the most food correspond with the largest catches of herrings, when there is the greatest amount of plankton. The herrings only come to these northern waters to feed at this time of year as they spawn in the warmer waters of the south and west.

The stomachs were taken from the freshly caught fishes, those from each catch (10–20) being placed in a separate bag and preserved in formalin. Later, the volume of each stomach contents was noted and the food roughly analysed both quantitatively and qualitatively. The percentage of herrings from each net feeding on certain food was then estimated.

As was to be expected, copepods form the largest part of the herring food. Nearly all the purse-seine fishes were feeding on them, euphausiids coming next in importance, amphipods, crab larvæ and pteropods also being eaten. The drift-net fishes fed largely on copepods at times and they also ate the other food mentioned above. Besides these there were present in smaller quantities in the fishes from both nets decapod and cirripede larvæ, cladocerans, gastropods, polychætes, chætognaths, fishes and fish eggs. Sometimes crab larvæ (almost entirely *Hyas coarctatus*, both zoeæ and megalopæ, which occurred in swarms at certain seasons) and *Ammodytes* were eaten in numbers.

Of the copepods, *Calanus finmarchicus* is much the most important food. It is found in huge masses in the waters north of Iceland, colouring the sea red, and it constitutes at least 95 per cent of the copepods eaten. Others taken by the herrings are *Temora longicornis* (very occasionally predominating), *Calanus hyperboreus*, *Metridia longa*, *Pseudocalanus elongatus*, *Microcalanus pygmæus*, *Acartia longiremis* and *Oithona similis*. Euphausiids (*Meganyctiphanes norvegica*, *Thysanoessa* (=*Rhoda*) *inermis*, *Thysanoessa* (=*Rhoda*) *raschii* and *Thysanoessa Longicaudata*) are eaten by the fishes from both nets, the adults chiefly by the drift-net herrings, the younger stages, which inhabit the surface layers, by the seine-net herrings. The pteropods *Limacina retroversa* and *Limacina helicina* occur sometimes very commonly in these seas and occasionally fill the stomachs of the drift-net herrings, especially in August and September.

University and Educational Intelligence

CAMBRIDGE.—The Botany School has received from the estate of Mr. S. H. Bickham a valuable collection of several thousand specimens of plants and eighty-five botanical books. The bequest is a very important addition to the herbarium, since nearly all the specimens are of British plants and the herbarium has specialised in British and colonial species.

Prof. D. B. Copland, of the University of Melbourne, has been appointed Alfred Marshall lecturer for 1933–34.

A University lecturer and a University demonstrator in the Department of Anatomy will be appointed shortly; applications should be made to Prof. J. T. Wilson, Anatomy School, Cambridge, by July 10.

The electors to the Wyse studentship in social anthropology announce that they have awarded studentship of £250 for one year to Miss M. M. Hunter, Port Elizabeth Collegiate School and Girton College.

LONDON.—The following City companies have made grants to the University, payment in each case being spread over a period of years:—The Merchant Taylors' Company, £5,000; the Stationers' Company, £100. These benefactions will be applied towards meeting the cost of the new ceremonial hall to be erected on the University's site in Bloomsbury. A grant of £100 has also been made by the Guardian Assurance Company towards the cost of the new buildings.

OXFORD.—The Committee of Management of the Lewis Evans Collection of Scientific Instruments has published its annual report. Many accessions are enumerated, including gifts to the library and to the collection of portraits. The need is pointed out of an endowment for a curator.

SHEFFIELD.—The following appointments have recently been made:—Dr. L. C. D. Hermitte, demonstrator in pathology, the post to be held in conjunction with that of assistant pathologist to the Royal Infirmary; Dr. Eric James, junior assistant bacteriologist and demonstrator.

Prof. E. Mellanby has resigned from the chair of pharmacology, and Mr. J. W. Kershaw from the senior lectureship in mechanical engineering.

THE Association of Technical Institutions will hold its summer meeting at the Municipal College of Science, Manchester, on June 29–July 1, under the presidency of Sir Hugo Hirst, chairman of the General Electric Co., Ltd. The following papers will be read and discussed at the meeting: "The Training of the Technical Teacher" by J. H. Currie; "The Textile Industry" by Prof. W. E. Morton; and "Management Education, the Case System", by Principal G. A. Robinson. Further information can be obtained from Dr. H. Schofield, Loughborough College, Loughborough.

---

* P. Jespersen, "On the Food of the Herring in Icelandic Waters". Meddelelser fra Kommissionen for Danmarks Fiskeri og Havundersegelser. Serie Plankton. Bind II. No. 3. 1932.

A Busk studentship in aeronautics, established in memory of Mr. E. T. Busk, will be awarded during July. The studentship is valued at £150 for one year, but may be extended to two years. The student will be expected to carry out research in aeronautics, especially in stability problems, meteorological questions bearing on flight, or the investigation of gusts. The investigations may be carried out either at home or abroad. Further information can be obtained from Prof. B. Melvill Jones, Engineering Laboratory, Cambridge.

A RECENT (November, 1932) number of "University of Colorado Studies" is devoted to the publication of a collection of abstracts of theses for higher degrees, an enterprise which few university administrations consider to be worth its expense. Here we have a hundred and seventy abstracts, on an average 350 words each, constituting a cross-section of the course of advanced study and research in progress in the University. More than one-fifth of the theses are records of research in pedagogy. Of the remainder, half deal with humanistic and half with scientific topics. Theses on engineering subjects number 17 (electrical engineering 13), biological 14, chemical 10, physical and geological 6 each. A fairly large number of them are records of regional surveys.

THE *Universities Review* has in its April issue several articles of unusual interest. Prof. S. Brodetsky describes the plight of Jewish university teachers in Germany and the prominent place taken by Jews in intellectual life in that country. He explains the growth of the pseudo-scientific anti-Semitism which found such a successful exponent in Houston Stewart Chamberlain, whose work "The Foundations of the Nineteenth Century" formulated German racial pride and its application to Jews in a way that won the approval of the Kaiser and his advisers and added venom to an already virulent complex, aggravated and sharpened since the War by the rapid growth of an academic proletariat in excess of the capacity of the country to absorb them in useful occupations. The work of its International Relations Committee forms the subject of the presidential address to the Association of University Teachers which is reproduced in this number, and there is a report on continental students in British universities. Academic freedom in the United States is discussed by Preston Slosson who corrects the distorted picture drawn by Upton Sinclair in his "Goose Step" by showing that plutocracy is only one of a host of dangers by which freedom is beset. An informative article by F. A. Went and R. C. McLean on the Dutch university system is a useful addition to the series of similar papers which the *Review* is publishing. Eugen Rosenstock writes about the "mortal disease" of specialisation and urges by way of remedy the grouping of opposites into a sort of common life as in settlements, summer schools and camps.

Calendar of Nature Topics

Shamal

The prevailing wind in the Persian Gulf and the Sea of Oman blows from the north-west and is called by the Arabs 'shamal'. A shamal may occur in any month of the year, but it blows almost without cessation during June and the early part of July, when it is known as the 'great' or 'forty-day shamal'. A shamal may set in suddenly at any hour of the day or night, and generally lasts from one to five days. Although the wind is not usually strong, rarely exceeding thirty miles an hour, it is very hot and dry, and carries great quantities of dust from the deserts of Persia and Mesopotamia. The sky is cloudless, but the haze is often so thick as to obscure the land, making navigation dangerous, and the decks of ships far out at sea are covered by a fine impalpable dust.

Frequency of Birds

The number of birds in an area fluctuates considerably throughout the year, under the influence of changing quantities of food, whether vegetable or animal, of birth rate and death rate, and of migration. But in inland parts of the northern hemisphere the numbers reach their climax in June, a fact to be correlated with the height of the nesting season in the latter half of May (see "Nature Calendar", March 25, p. 445). In June the newly-fledged broods of the year still keep together in their home area, but as the year progresses their ranks are thinned by death and the relicts scatter over a wider territory.

An interesting confirmation of the June climax in bird numbers comes from Yosemite Valley in the Yosemite National Park, California. There, since the summer of 1920, Mr. and Mrs. Charles W. Michael have kept daily records of all species of birds seen by them. At the end of each month a summarised report of all observations for the preceding thirty days has been sent to the Museum of Vertebrate Zoology, Berkeley, California; and now Dr. Jean M. Linsdale has used the daily records for the period August 1, 1920--November 30, 1931, to estimate the relative frequency of occurrence of the birds in the Valley (*Condor*, **34**, 221; 1932.) The species seen numbered 151, but of these only 40 were observed on more than 20 per cent of the days. A rough test of the relative numbers of birds present will be given by comparing the monthly numbers of species seen every day during the month. Extracting from Dr. Linsdale's statistics, we find that these numbers form a simple unimodal curve, at its lowest in January and December with 1 and 0 species seen every day, and rising to an apex in mid-summer with 13, 20, 12 in May, June and July respectively. This indication that June is the month of highest bird population in Yosemite Valley is confirmed by analysis of the monthly totals of observations of the forty most common birds.

Breeding Season of Sea-Lions in California

From the middle of June to the middle of July the breeding season of the sea-lions of California is at its height. Then the breeding adults, grouped in harems of females dominated by a master bull, form rookeries upon the islands off the coast, and when the single pups are born the sea-lion population is at its maximum. It was at this period that, in

1930, a census of the sea-lions was made (Paul Bonnot in *California Fish and Game*, 1931, p. 150). Two species were involved, the California sea-lion (*Zalophus californianus*), the smaller of the two, weighing about 500 pounds, and Steller sea-lion (*Eumetopias jubata*) the male of which weighs between 1,500 and 1,800 pounds. The census revealed that, as a rule, one species avoids the rookeries of the other. Of seventeen island rookeries, the two species occurred together on six only, and generally one was dominant and the other represented by a relatively small number of individuals. The California sea-lion is a southern species, less numerous in California, with 968 individuals, than the Stellers with 6,360, and the latter becomes predominant northwards, where it ranges to the Bering Straits. Counts of individuals made in 1927, 1928 and 1930 show that while the Stellers are increasing in numbers the Californias are decreasing. Since both species are subject to the destruction caused by professional hunters and collectors, the difference seems to be due to the limited range of the Californias, which have been harried to such an extent that several of the larger rookeries have been materially reduced or abandoned, whereas in spite of local destruction the rookeries of the Stellers are replenished by an influx of new individuals from the north, where, under a bounty system, the species is even more intensively hunted.

Early Potatoes

Farmers in England are now about to realise the first cash crop of the season. In a few favoured districts first early potatoes will be ready to lift. Their production is a highly specialised business, the controlling factor being a rare combination of soil and climatic conditions: a warm, free-draining soil sheltered from the north and east, with comparative freedom from frost and drought in May. With these natural advantages growers provide every artificial aid in forcing on the crop. Heavy dressings of bulky organic manures are given and these are further reinforced by generous additions of chemical fertilisers. In the famous 'early districts' the potato crop is taken much more frequently than is normally the case; nevertheless, little faith is placed in manurial residues and each crop is treated with the same generosity. The fact is that the period of high prices at the opening of the season is a very restricted one and no economy is considered worth while which might cause the crop to miss the first demand. Crops are always lifted immature, indeed a further fortnight's growth would almost double their yield but might actually reduce the acre value. Only the earliest home-produced crops come in in June, the Cornish supplies being the first; most of the supplies arrive in July and with them the price gradually comes down to a level not very different from that of the main crops which follow.

Cropping the same land at frequent intervals, the early growers do not escape the troubles almost invariably associated with the localisation of any crop. Of these, the eelworm disease is one of the most serious and is now a grave pest in many districts except perhaps on the very earliest crops. In one respect, disease has affected the industry in a favourable direction. The exclusion of foreign early potatoes likely to be affected with Colorado beetle has to that extent enlarged the market for home-produced supplies.

Societies and Academies

LONDON

Geological Society, April 26. L. S. B. LEAKEY: Fossiliferous deposits in the Homa-Kendu Area, Kenya Colony. The best exposures were found at Kanjera, the site previously discovered by Dr. Oswald, and at Kanam, some three miles farther to the west. The deposits, which must have been laid down in a former very great extension of Victoria Nyanza, were considerably affected by faulting and had a dip varying from 20° to 90°. At Kanjera fragmentary skull-caps of three individuals, as well as a fragment of a human femur, were recovered, and at Kanam a small fragment of a human mandible. These remains are remarkable because they represent very early human beings, who, in spite of their primitive characters, seem to approach *Homo sapiens* more closely than any other fossil humans of comparable age. The Kanam deposits and, therefore, the Kanam mandible are regarded as Lower Pleistocene, whilst the Kanjera deposits and the Kanjera skulls are to be attributed to the Middle Pleistocene.

DUBLIN

Royal Irish Academy, March 16. J. G. SEMPLE: Composite surfaces in higher space. The relations, obtained by Severi, which connect the projective characters of two algebraic surfaces in r dimensional space ($r \geqslant 4$) when they together form the complete intersections of $r-2$ primals of specified orders, are extended in this paper to cover the case when the primals intersect in any number of surfaces. The equations so obtained can then be re-arranged to show that definite virtual projective characters can be assigned to a general composite surface consisting of any number of irreducible surfaces intersecting in specified curves. The virtual unreduced canonical system of a composite surface is also defined, and examples are given of the manner in which the unreduced canonical system of an irrational surface breaks up when the surface degenerates into a composite surface. The bearing of the results obtained on the problem of the limiting envelope of a degenerate surface is also considered.

PARIS

Academy of Sciences, May 1 (*C.R.*, **196**, 1253–1344). JULES DRACH: A class of congruences of right lines. C. MATIGNON and J. CALVET: Ageing of the aluminium-beryllium alloys after tempering. The aluminium-beryllium alloys studied, prepared from highly purified materials, after tempering, underwent a very rapid ageing at the ordinary temperature; fifty per cent of the transformation took place in ten minutes. P. A. DANGEARD: Remarks on the presence of a centrosomic apparatus in species of the genus *Lonicera*. The results recently published by Feng have been criticised: the author confirms the accuracy of the observations. J. COSTANTIN: Is the immunity of the sugar-cane *POJ* 2878 absolute? R. FOSSE, P. DE GRAEVE and P. E. THOMAS: The rôle of allantoic acid in the higher plants. E. J. GUMBEL: The representations of unimodal distributions unilaterally limited. P. DUBREIL: Some properties of the characteristic function of Hilbert. P. VINCENSINI: Stratifiable congruences. V. LALAN: Affine developants of minimal curves. B. GAMBIER:

A congruence of circles osculating the lines of curvature u = const. of a surface S_1 and v = const. of a surface S_2. **DELSARTE** and **RACINE**: A special binary ds^2. **CHR. FOUSIANIS**: A theorem of E. Borel. G. D. **MATTIOLI**: The theory of turbulence in channels. **FLORIN VASILESCO**: Movements in three dimensions, with a wake. **HENRI CHRÉTIEN**: An impersonal astrolabe. A. **PÉRARD** and M. **ROMANOWSKI**: First comparisons of the national standards of electrical resistance, carried out at the Bureau international des Poids et Mesures. The standards compared were from Berlin, London, Paris, and Tokyo: the Washington (Bureau of Standards) standards were not available. Differences of 0·1 microhm could be detected. The difference between the French and Japanese ohm is nearly a ten-thousandth. **PAUL JANET**: Remarks on the preceding paper. N. **STOYKO** and R. **JOUAST**: The apparent velocity of short radio-electric waves. The apparent velocity of radio-electric waves is always less than the velocity of light owing to differences of path. For short waves (15–40 m.) between Paris and Buenos Aires, the apparent velocity was 269,700 km./sec., a value agreeing with that previously found by the indirect method. For long waves, the velocity found was 245,000 km./sec. The differences can be explained by the difference in the mechanism of propagation of the two varieties of waves. TH. V. **IONESCU** and MME. **IRÈNE MIHUL**: High-frequency discharge in gases. Studies on the effect of a magnetic field on the maintenance of the discharge. A magnetic field reduces the potential necessary for the maintenance of the discharge in a tube. H. **HULUBEI** and MLLE. Y. **CAUCHOIS**: Weak lines in the K spectra of the elements 45, rhodium, and 42, molybdenum. Confirmation of some earlier results and description of some new lines. C. **HAENNY**: The magnetic double refraction of some cerium salts in aqueous and non-aqueous solutions. The magnetic double refraction of a saline solution is markedly affected by the presence of an excess of the acid forming the salt. For cerium, the magnetic double refraction and the paramagnetism is essentially due to the presence of the electron detached from the cerous ion. **JACQUES WINTER**: The diffusion of electrons by atoms. **CHARLES LAPICQUE**: The non-additive effect of different radiations on copper oxide cells. R. **DEAGLIO**: The photoelectric effect in the monocrystals of cuprite. The experimental results described prove that the photoelectric effect discovered by Dember is simply a consequence of the property of cuprite of acquiring an electrolytic conductivity when it is illuminated. R. **COUSTAL**: A connexion between the two general methods for the preparation of phosphorescent zinc sulphide. The author has fused zinc sulphide in nitrogen under a pressure of 160 km. at a temperature of 2000° C. and has obtained a phosphorescent sulphide with an optimum concentration of the copper phosphorogene of about 10^{-6}. —. **POIDEBARD**: A new method of taking aerial photographs in tropical climates. The photographs are taken at a low altitude and facing the sun. MME. **BRANCA EDMÉE MARQUES**: The distribution of the radium in the fractional precipitation of radiferous barium chloride. An experimental study of the precipitation of mixed barium and radium chlorides by hydrochloric acid. P. **LOCUTY** and P. **LAFFITTE**: The system ammonium sulphate, sulphuric acid, water. MLLE. M. **PERNOT**: The system mercuric bromide, potassium bromide, ethyl alcohol. **JEAN BOUCHARD**. The quantitative study of the inhibiting action of some organic compounds on the fluorescent power of uranine. MME. L. S. **MATHIEU-LÉVY**: The catalytic oxidation of carbon monoxide. The evolution of the catalyst. **RENÉ PERRIN** and **ALBERT PORTEVIN**: The evolution of the inclusions in the elaboration of steels. B. **BOGITCH**: The use of hot air in the fusion of minerals with a water jacket. P. CH. **DORIER**: The action of 1·3 dichloropropene on the sodium derivatives of the aryl fatty acids. **CHARLES DUFRAISSE** and J. A. **MONIER, JR.**: Researches on the dissociable organic oxides. *Bis*–1.1′.(*p*–tolyl)–3.3′.diphenyl–5.5′–dimethyl–rubene: its dissociable oxide. The introduction of the two methyl groups has not affected the property of the rubenes of fixing free oxygen reversibly. **MAURICE LOURY**: Researches on the acetylene carbinols: phenylcarbethoxyphenylethinyl carbinol, $C_{18}H_{16}O_3$. MME. F. **BAYARD-DUCLAUX**: Study of methods for putting in circuit specimens of rock for measuring their electrical resistance. The specimen is held by two stirrups, one of which is fixed and the other loaded to known amounts. The pressure is constant and the insulation sufficient. For rocks permitting the production of an optically polished surface good contact can be obtained with electrodes of silver foil under low pressure. For other rocks a higher pressure is required and the minimum pressure must be determined for each specimen. **PHILIPPE HAGENE**: Characters of the humus of pollarded willows. EM. **SAILLARD** and R. **SAUNIER**: The determination of the ash of sugar beet juice by measurement of the electrical conductivity. MME. **NELICIA MAYER-REICH**: The action of oxygen on glucides developed in the absence of air. P. **NÖEL BERNARD** and J. **GUILLERM**: The transmissible lysis of the cholera vibrion. It is possible to extract from pure cultures of the cholera vibrion, by the usual methods for the extraction of diastases, a lytic substance. This is specific, has an optimum pH of action, and reproduces exactly the phenomenon of bacteriophagy. MLLE. A. **MICHAUX**: The amounts of total phosphorus in the blood and muscles and the elimination of this element by the renal canal in the course of acute scurvy and chronic scurvy.

CRACOW

Polish Academy of Science and Letters, Feb. 6. S. **BANACH**: Green's formula. LAD. **NATANSON**: Permanent fields of radiation. W. **SWIETOSLAWSKI** and E. **WARDZINSKI**: The ternary heteroazeotrope: ethyl alcohol, water, carbon disulphide. A description of a modified differential ebullioscope with fractionating column, and its application to the above mixture. W. **JACEK**: The velocity of solution of marble in acids (3). Study of the rate of solution of marble in hydrobromic acid as a function of the concentration. L. **MARCHLEWSKI** and J. **DABROWSKI**: Studies in tautomerism, carried out by means of the spectrophotometric method. The results of Hartley and Dobbie on the constitution of isatin are confirmed. K. **DZIEWOŃSKI** and J. **MAYER**: A new method of synthesis of compounds derived from quinoline. CZ. **KUZNIAR**: Rock salt from Morszyn. J. **TUR**: The correlation between the formation of the vitelline vessels and that of blood corpuscles. B. **SKARZYŃSKI**: Studies on the transformation of carotene into vitamin A in animals.

GENEVA

Society of Physics and Natural History, March 2. M. **GYSIN**: Petrographical researches in the Haut-

Katanga. Note 3. The formations of the Roan series. (1) The author shows the great lateral variations of facies and thickness which the formations of the Roan series undergo in the south-eastern part of the Haut-Katanga. He gives a mean stratigraphic scale subdividing the Roan series into six horizons. The rocks which form these six horizons may be classed in sixteen distinct petrographical types. G. TIERCY: The mean absorption coefficient in a variable star of the Cepheid type. The author studies the relation which exists between the ratio of the total flux corresponding to two phases of the variation, the ratio of the respective mean absorption coefficients, and the ratio of the corresponding pressures of the reversing layer. G. TIERCY and A. GROSREY: Study of the width of a photographic stellar spectrum for stars of the type *A*5. The authors establish for stars of this type a formula giving the variation of the width of the spectrum as a function of the time of exposure and the magnitude, the stellar image being supposed to be kept on the cross wires of the finder during the whole of the exposure. ROSSIER: The diameter of some stars of the cluster *M*.7. The author compares the results obtained by M. Wallenquist with those given by his formula. The results are somewhat uncertain on account of the want of knowledge concerning the sensibility curve of the receivers used.

VIENNA

Academy of Sciences, Feb. 9. EDMUND FRAENKEL and JULIUS ZELLNER: Contributions to comparative plant chemistry. (24) *Heracleum spondylium*, L. The roots of this plant contain two substances of the ostruthin type (to be investigated), considerable proportions of resin, a sterol, a wax-like material, a choline-like base, glucose, and starch. JOSEF KLIMA: Chemistry of the lichens (2). *Alectoria ochroleuca*, Ehrh. In addition to the two known lichen acids, this lichen contains an amorphous lichen substance of non-acid character, a solid hydrocarbon, a sterol, oleic and linolic acids, small amounts of solid fatty acids, a crystallisable sugar-alcohol (probably erythritol), glucose, basic substances of choline type, and lichenin in abundance. LEOPOLD LUKACS and JULIUS ZELLNER: Chemistry of the higher fungi (22). *Ganoderma lucidum*, Leiss, *Hydnum imbricatum*, L., and *Cantharellus clavatus*, Pers. The *Ganoderma* species contain a specific resin and large proportions of a brown colouring matter, which is insoluble in all indifferent solvents and soluble only in alkali hydroxide and resembles certain humic acids; in addition, ergosterol, mannitol, fatty acids, polysaccharides and other substances commonly found in fungi, are present. The two other species yielded no specific ingredients, other than colouring matters of amorphous consistency and low stability. WOLF J. MÜLLER: Theory of passivity phenomena (18). Fluctuation phenomena in anodic passivification. Results are cited which indicate that the thickness of the layer varies during anodic passivification. Hence the covering laws are valid only within certain statistical limits of fluctuation, and passivity phenomena must be investigated statistically, a large number of experiments being made for each separate case. HERMANN VEIT GRABER: New observations in the region of the crystalline shales and massive rocks of Eisenkappel in southern Carinthia.

Forthcoming Events

The World Economic Conference

THE World Economic and Monetary Conference now meeting in London is undoubtedly the most comprehensive and authoritative congress of its kind which has ever been convened. Sixty-six governments, ten of which are not members of the League of Nations, have sent representatives. Never before has there been such a meeting of heads of governments, ministers of foreign affairs and ministers of finance, with their technical advisers and experts.

The Conference is the sequel to the work done last year at Lausanne, when an immediate financial collapse was averted by means of a temporary agreement on War debts. The Council of the League of Nations then agreed to the recommendation of the Lausanne Conference that it should convene a wider conference to tackle the whole problem of the world crisis. A Preparatory Commission of experts was appointed to report on an agenda for the business of the World Economic Conference and the report of this Commission has been made the basis of the deliberations of the present Conference.

The magnitude and difficulty of the problems discussed in this report and now confronting the Conference are only matched by the urgency of the crisis and the desperate need of the world for harmonious international action designed to secure the alleviation of its economic malaise. The number of workers now without employment has been estimated by the International Labour Office to be at least thirty millions, but even this figure gives but a very inadequate conception of the universal distress, as it takes no account of dependants or of the distress afflicting the agricultural populations of the world.

Since October, 1929, the level of wholesale prices has fallen by about one-third, thus seriously reducing the purchasing power of countries engaged in primary production and imposing a serious check to trade in practically all countries. World stocks of agricultural products and other raw materials continue to accumulate without prospect of a sale for the surplus ; industrial production has been drastically curtailed and has declined by something like a third ; national incomes have fallen seriously, in some cases by so much as 40–50 per cent. The total world trade in the third quarter of 1932 was only about one half the volume of that in the corresponding quarter of 1929, while its value was only about one-third. Only about a dozen countries have retained free and uncontrolled gold currencies, with the result that fluctuating exchanges and competition between nations in currency depreciation have further served seriously to disorganise international trade, which has also been nearly strangled by high tariffs, exchange restrictions, quotas and even prohibitions, not to mention disturbances in the normal channels of trade imposed by subsidies or other methods designed to promote national economic policies. As Mr. MacDonald stated in his opening address, "no one who has surveyed the facts and watched their progress can doubt for a moment that the experiences of the last few years have proved that a purely national economic policy in this modern world is one which by impoverishing other nations impoverishes those who pursue it".

The programme of reconstruction suggested by the Preparatory Commission did not include the problem of inter-governmental debts, because this lay outside its terms of reference, but it stated that, "until there is such a settlement, or the definite prospect of such a settlement, these debts will remain an insuperable barrier to economic and financial reconstruction". During the first week of the Conference, the general conviction unquestionably appeared to be that any solutions proposed by the Conference, if they are to be effective, must be accompanied by the settlement of War debts. Mr. MacDonald, Signor Jung, General Smuts and others have been emphatic on this question. Though it lies outside the scope of the Conference, this question of debt settlement is nevertheless inseparably linked with its work of world reconstruction. The first step towards its final settlement has now fortunately been provided by the statesman-like action of President Roosevelt, who in the face of all his domestic difficulties, accepted the British Government's proposal of a payment of ten million dollars in silver in recognition of British liability, pending a final adjustment of the matter. The merit of this arrangement is that it is neither default, which would be disastrous, nor payment in full, which would have left the old problem with us and might have jeopardised the success of the Conference.

In the field of monetary and credit policy, the Preparatory Commission recommended that the objective should be the restoration of an effective international monetary standard, together with a policy of easy money designed to promote a healthy expansion of business. In its opinion, the abolition of exchange control is an essential condition of world recovery. To obtain this, it is necessary to secure balanced budgets and to restore the confidence of the foreign lending markets to prevent sudden withdrawals of short-term debts.

The Commission considered that there must be greater freedom of international trade and recalled that one of the most significant features of the present crisis is the fall which has occurred in the value and physical volume of world trade. Governments should set themselves to re-establish the normal interchange of commodities and every effort should be made to secure a general agreement for the progressive relaxation and the complete abrogation at the earliest possible date of such restrictions as prohibitions or quotas imposed on trade as a result of the crisis. In addition, it is necessary to reduce excessive tariffs. The Commission rightly concluded that any action in the direction of a return to freedom of trade has an intimate bearing on the stabilisation of currencies, as it is impossible to maintain the international monetary system except on the basis of an international economic system. In this respect the great creditor nations have a special responsibility.

The methods proposed by the experts for the restoration of world currencies are that countries on the gold standard should pursue a liberal credit policy, while those not on gold should smooth out short-term exchange fluctuations and avoid competition in exchange depreciation. When the gold standard is restored, the gold reserve requirements of central banks should be lowered while some countries should avoid demands upon the world's gold supply by adopting an improved system of the gold exchange standard. In assisting the smooth working of the gold standard, the Commission assigned an important part to the Bank of International Settlements. The general tenor of the experts' recommendations is an early and general return to an improved gold standard under such conditions as will provide safeguards against future disastrous fluctuations in the value of the monetary metal and secure a rise in world prices.

In all the opening speeches at the Conference, it was generally agreed that the problems to be solved are to stabilise currencies in relation to some common international standard, to remove barriers to world trade and to raise world prices. Equally important, all were agreed that there must be an end to the prevailing conflict of national economic policies.

Nothing in these suggestions is really new and indeed it would be surprising if it were so, for ever since the depression began the whole world has been searching for remedies. But it is much to the good that the problems have been clearly realised and frankly stated. Now the real work of the Conference begins, and that is to work out the details and secure the adoption of practical policies which will lead to the amelioration of the world crisis. General Smuts urged that when the delegates had the reports of the technical committees before them, they should not make too much of their political difficulties but should face the issues fairly and squarely on their merits. It is much to be hoped that this will be done. The great need to-day is the restoration of world confidence, and if the Conference can do anything to achieve this, its labours will not have been wasted. To-day the nations are bound together in a world economy wherein the prosperity of each nation ultimately is bound up with the prosperity of the world as a whole.

Sir Charles Parsons

Charles Parsons: his Life and Work. By Rollo Appleyard. Pp. xiii+334+17 plates. (London: Constable and Co., Ltd., 1933.) 15*s.* net.

IT is related that when the famous little *Turbinia* was taken to France during the Paris Exhibition of 1900, Augustin Normand, the eminent naval constructor of Havre, after meeting Parsons, remarked of him "Il ne pense qu' a' la turbine; il y pense sans cesse".

For nearly twenty years, Parsons had been absorbed in the development of the steam turbine; for another thirty years it was the chief interest of his life; and it is for his work on the turbine and the turbo-generator that he will be remembered. Although its possibilities were entirely unforeseen by any of his early contemporaries, Parsons' steam turbine led to a revolution in the production of power, in the methods of generating electricity and in the propulsion of ships. In later years his reaction turbine had serious rivals in the impulse turbines of de Laval, Curtis, Rateau and others, but a study of the history of turbines and the many problems connected with them only increases our admiration for his brilliant pioneering work, and reminds us of the profound influence his investigations had on subsequent developments.

The value of any memoir of Parsons must therefore depend largely on the light it throws upon the inception of his remarkable invention and the steps by which the seemingly insuperable difficulties were overcome, and also upon the effect the introduction of the steam turbine had on the problem of power. Judged by this standard, Mr. Appleyard's book is a most welcome addition to the literature of the subject and one which can be read with pleasure even by those who are not engineers by profession. Parsons himself and his colleagues, from time to time in their various papers and lectures, dealt with the progress of turbine machinery, but to these reviews Mr. Appleyard has been able to add those personal records from which we are able to gain an insight into the methods by which success was attained.

Though Parsons started with exceptional advantages, the path he chose was by no means an easy one and the obstacles he encountered might well have discouraged the most dauntless. But no task was too hard; no problem too complex. He had "immediate insight into requirements" and, as Mr. Appleyard says, "When due thought had been bestowed upon a design, when due care had been exercised in construction, he put his work to the test with determination and courage".

While it may be said that Parsons never ceased to think of the turbine, his versatility as an inventor and his insight into physical problems was shown in many ways. Quite early in his career, following in his father's footsteps, he applied himself to the manufacture of mirrors for searchlights, and towards the end of his life found an outlet for some of his energy in the construction of large telescopes. From long experiments on the artificial production of diamonds, he could turn to the invention of the auxetophone, a form of air-operated loud speaker which was used for a season at the Queen's Hall concerts, and to the "great engineering attack on a problem of geology", the sinking of a shaft in the crust of the earth twelve miles deep.

With all these matters, Mr. Appleyard deals with sympathy and understanding, as he does also with the character and career of Parsons. In some respects the story of Parsons is unique. An aristocrat by birth, at Birr Castle, at Dublin, at Cambridge and at Elswick, he came into contact with men of science and engineers of the first rank and with these he quickly took his place. It is true he was only one of many who attacked the urgent problem of the high-speed engine, but he was the first to solve successfully the problem of the steam turbine. By the time he was thirty years of age he had made his first turbo-generator, at forty he was applying the steam turbine to propulsion and at fifty he saw his turbine the successful rival of the triple expansion engine on land and sea.

The story of how Parsons lost and then recovered the control of his patents relating to the parallel-flow turbine is of absorbing interest. To Messrs. Clarke, Chapman and Co., with whom for five years, 1884–89, he was a junior partner, the patents without Parsons were of little value; to him they were everything, and when, through the efforts of Lord Moulton, Sir Dugald Clerk and Sir Alfred Ewing, he regained control of them, the future was assured. From that time onwards there was no looking back. At the time of his death, as Mr. Appleyard says, the total output from turbo-generators constructed by the Parsons firm, and by their licencees, for land purposes alone, exceeded thirty million horse power. But this is only half the story, for the horse-power of turbines of the Parsons type constructed for naval vessels and ships of the mercantile marine runs into many more millions.

One or two misprints, such as "Bellis" for "Belliss", and "*Sohol*" for "*Sokol*" have been overlooked in the proofs of the book, and for some reason reference is made to "Sir" George and "Sir" Robert Stephenson, which surely is a mistake. These are but trivial blemishes in an admirable memoir.

Tabular Data of Science

Annual Tables of Constants and Numerical Data: Chemical, Physical, Biological and Technological. (*Tables annuelles de constantes et données numériques de chimie, de physique, de biologie et de technologie.*) Vol. 8: *Années 1927–1928.* Part 1. Pp. xl+1101. Part 2. Pp. xxi+1102–2706. 500 francs. Vol. 9: *Année 1929.* Pp. 1+1607. *Tables des matières du Vol. 9, année 1929.* Rédigée par G. Kravtzoff. Pp. xxiv+124. Vol. 9, with Index, 400 francs. (Paris: Gauthier-Villars et Cie; New York: McGraw-Hill Book Co., Inc., 1931–1932.)

THESE volumes of the "Annual Tables", and especially vol. 9 containing the data recorded during 1929, have several features of interest and importance. Their binding is the familiar dark green cloth that clothed their predecessors, but there are interesting differences in their content. Vol. 1 of the series contained the data published during 1910 and was in many respects an experiment; it was clear that some such annual compilation was an urgent need in every scientific library, but the best way of presenting the data, the best way of arranging chemical compounds of all types and all the editorial details, could only be reached by experiment and with the help of friendly criticism. As the succeeding volumes appeared, alterations and improvements were made. Then the War came and, as happened to most international experiments, publication had to be suspended.

After the War, Dr. Marie and his staff were faced with a terrifying accumulation of data to be sifted, arranged and printed; they must have felt that to catch up with the ever-increasing mass of material was an almost hopeless task. They continued, however, and each volume that has appeared has shown some improvement on its predecessors. With the publication in 1931 and 1932 of the volumes under review, they have caught up with the data to the end of 1929, and have in addition produced a volume, vol. 9, which can be taken as their most polished product incorporating the lessons of nearly twenty years' experience.

The most important and striking feature of this last volume is its accompanying index. Compilers of comprehensive tables of numerical data are faced with one grave difficulty: the material must be arranged on some logical plan and, because of the enormous variety of properties measured and of substances examined, the plan itself must become a trifle complex. Such tables, however, are valueless unless they are used and the user, especially the occasional user, is apt to regard the plan in a rather different light from that intended. It seems to him at times to be a barrier that encumbers his way to the facts that he desires. He must obtain some knowledge of the plan before he can make use of the volume, and if he is in a hurry, and particularly if he cannot find what he wants, the plan, however logical, becomes a source of irritation. (It was in the United States that the reviewer heard a valuable compilation referred to as the "Intentionally Cryptical Tables".) This difficulty is, of course, most marked in a compilation as comprehensive as the "Annual Tables"; Richter's "Lexikon der Kohlenstoff-Verbindungen" can have one all-embracing plan and a knowledge of it is an integral part of the technique of the organic chemist; but no one plan can embrace all the sections of the "Annual Tables".

This unfortunate state of affairs is, however, completely altered by the existence of an efficient index volume such as that which accompanies vol. 9. In the main work the data are arranged, as they must be, in sections dealing with the various properties of substances and the phenomena they present. The index volume is the complement to the main work and gives alphabetical and formulæ indexes of all the substances examined during the year covered. Thus all users are satisfied, and particularly the user who wishes to know whether the density of a certain compound or the conductivity of a certain solution has been determined; he need no longer wade through lists of densities or of conductivities; reference to the index volume will tell him at once if the data in which he is interested are included or not, and if they are, precisely where to find them.

The index itself requires a system, but the one adopted will commend itself to everyone. It is based on the world's past experience in similar tasks; it incorporates bodily well-established systems such as that of Richter and Stelzner for the organic compounds; it is lucidly explained in the four more important European languages and is helped out by a plentiful supply of polylingual cross-references. The compilation of this index volume must have been a considerable labour, but the reward of gratitude will be great.

Other points to which attention may be directed are, first, that nowadays the whole text is given in both French and English. The advantage gained by this is not so marked in many of the sections dealing with the purely scientific data as it is in the more technical chapters. The vocabulary of the French physicist is to a large extent almost the same as that of his English colleague, their words coming from a common Latin root; but the engineers must at times have difficulties in understanding each other's technical terms, and these difficulties the bilingual text removes. Secondly, it should be noted that libraries or individuals whose interests are confined to one field alone are catered for, in that most of the more important sections can be purchased separately. The third and most important point is the price at which these volumes can be obtained; vol. 9 with its index at the present rate of exchange costs something well under £5 and contains more than seventeen hundred pages of compressed and complicated printing. This is a ridiculously small sum and it is sincerely to be hoped that the financial state of the world will not lead to the withdrawal of the grants from the various participating countries which make it possible to publish the "Annual Tables" at such a low price.

Finally, it may be noted that the present trend of physics is reflected in the facts that data on emission and absorption spectra occupy more than a quarter of both the volumes under review, and that the Raman effect, which was given three and a half pages of the chapter "Scattering of Light" in vol. 8 (1927 and 1928), has monopolised that chapter in vol. 9 (1929) and has demanded thirteen pages.

T. W. J. T.

Statistical Tables

Tables for Statisticians and Biometricians. Edited by Prof. Karl Pearson. Part 1. Third edition. Pp. lxxxiv+143. 15*s*. net. Part 2. Pp. ccl+262. n.p. (London: Biometric Laboratory, University College, 1930–1931.)

STATISTICIANS have for long been familiar with Prof. K. Pearson's "Tables for Statisticians" as the standard exposition of the theoretical conceptions and practical procedures adopted by the Biometric Laboratory at University College. The handsome and expensive production of the tables, and the abundant introductory matter, were features which, from its first appearance, compensated for the partial or personal tone which characterised the treatment of controversial topics.

In the course of time, as was inevitable, certain extensive tabulations have been found to be of less use than was originally hoped, and others, based on faulty theory, have been shown to be definitely in error. It is the most serious fault of this new edition that no account seems to have been taken of these changes. Thus Tables 17, 18 and 19, concerned with the calculation of the probability of deviations from proportionality in a 2 × 2 table, are printed without change from the first edition, although it is now recognised, almost if not quite universally, that the use of three degrees of freedom in place of one is definitely erroneous.

Part 2, of which this is the first edition, is an even larger volume. The introduction occupies 250 pages, and the tables 262. Many tables supplement or enlarge those given in the first volume, and it would have been of great advantage to the user if the matter had been re-arranged so as to bring together tables dealing with the same function. Thus the reader of Table 30 of Part I is not told that, under a different title, sixty pages of Part 2 (Tables 8 and 9) contain a fuller and more accurate table of the same function.

The utility of some tables would have been greater had their nature not been disguised by the special terminology of the Biometric Laboratory. Thus a good, though truncated, table of the derivatives of the normal probability function (Table 7) is termed "Table of the First Twenty Tetrachoric Functions", owing to the accident that these functions were at one time used in the Biometric Laboratory for estimating the correlation coefficient from a 2 × 2 table. Others, such as the fifty-seven crowded pages devoted to Table 3 (more than 70,000 entries), seem like elaborate attempts to make available a cumbrous method of approach to problems already more simply solved.

Among the more useful tables should be mentioned Table 2 of the second part, giving the abscissæ and ordinates of the normal curve, and certain important ratios, arranged as in Prof. Kelley's textbook of "Statistical Method". The table is to ten figures and based on Sheppard's extensive tables, as yet unpublished, of the probability integral. Table 7, which we have already mentioned, will also be useful, though in the introduction the reader is warned against this heresy, in constructing curves from their Charlier expansions.

As a collection of the labours of the Laboratory the work is monumental. Like other ambitious monuments, however, it invites criticism at a number of points. R. A. FISHER.

Short Reviews

Man and Medicine: an Introduction to Medical Knowledge. By Dr. Henry E. Sigerist. Translated by Margaret Galt Boise. Pp. x + 340. (London: George Allen and Unwin, Ltd., 1932.) 12*s*. 6*d*. net.

DR. HENRY SIGERIST, who in 1925 succeeded the veteran Sudhoff as professor of the history of medicine in the University of Leipzig and has recently followed Dr. W. W. Welch in the corresponding chair at Johns Hopkins, has written a work which will be of value not only to the medical student for whom it is primarily intended but also to the layman interested in medical history and doctrines.

The work is divided into seven chapters. The first deals with man in his anatomical, physiological and mental and spiritual aspects with special reference to the work of Vesalius, Harvey, Freud and Jung. In the second chapter the sociological aspects of disease and the behaviour of the sick man are considered, with a comparison between the conception of disease in ancient and modern times. In the following chapter, entitled "Signs of Disease", the author shows that symptoms and disease are not identical conceptions but that symptoms are manifestations of disease, occurring in combination or following one another successively during the course of the disease. The fourth chapter is devoted to the consideration of the development of the various conceptions of disease throughout the ages, general theories of disease, the study of special diseases, the course of the disease, and its incidence and mortality. In the fifth chapter the causes of disease are discussed under the headings of external causes such as physical influences, food and drink, bacteriological and mechanical agencies, and internal causes, such as disposition, constitution and heredity. Medical aid, which forms the subject of the sixth chapter, is considered from the threefold aspect of diagnosis of the diseases, treatment and prevention. The last chapter contains a short historical account of the physician in ancient Egypt, classical antiquity, the Middle Ages, the Renaissance and modern times, a consideration of the subject of sick insurance, professional secrecy and medical ethics.

A word of praise is due to Miss M. G. Boise for the excellence of her translation.

Architectural Acoustics. By Prof. Vern O. Knudsen. Pp. viii + 617. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1932.) 40*s*. net.

THIS massive volume admirably illustrates the manner in which a specialised physical subject, even in 'non-atomic' physics, may rapidly proceed from a very unsatisfactory rule-of-thumb stage to a stage in which one may obtain some definite measure of guidance from an appeal to fundamental principles. This particular subject, which owes its existence in great measure to the pioneer labours of the late Prof. Sabine, is developed by the author in a very competent and comprehensive manner.

The book is divided into three parts. The first part, consisting of about a hundred pages, is devoted to the study of physiological and physical acoustics. In the second section, the fundamentals of the special part are developed, a series of chapters being devoted to reverberation, and to the absorption, insulation and amplification of sound. This part concludes with a discussion of the acoustics of auditoriums, speech halls and music rooms. The third part deals with the application of these principles to building design.

Two very useful features of the book are a series of problems on which the student may exercise his skill, and a list of clearly phrased definitions of terms used in acoustics, together with an expression of the units in which the quantitative magnitudes concerned are measured. We may not always agree with the author's usage; in particular we note that he is not a member of that guild of stern logicians which insists that a sensation loudness can not be made the subject of measurement. But there is no denying the value of such a list, and it is greatly to be desired that other authors should adopt this very useful practice. A. F.

Classical Descriptions of Disease: with Biographical Sketches of the Authors. By Prof. Ralph H. Major. Pp. xxvii + 630. (London: Baillière, Tindall and Cox, 1932.) 30*s.* net.

THIS fine volume, the composition of which was inspired by Long's "Selected Readings in Pathology" (see NATURE for March 29, 1930, p. 488), contains the original descriptions of various diseases, translated when necessary into English, from classical antiquity down to the present day. After an introduction containing passages from Hippocrates, the work consists of ten parts devoted respectively to classical descriptions of infectious diseases, diseases of metabolism, lead poisoning, diseases of the circulatory system, diseases of the blood, kidney diseases, respiratory diseases, deficiency diseases, allergic diseases and diseases of the digestive system. A short biographical notice is prefixed to each writer's account of the disease.

The extracts are not confined to the works of dead writers but include passages from the works of Charles Nicolle and his collaborators on the transmission of typhus by the louse, of Banting on the internal secretion of the pancreas, of Pierre Marie on acromegaly, of Leo Buerger on thrombo-angeitis obliterans and of Herrick on sickle-cell anæmia.

Dr. Major is to be congratulated not only on his selection but also on his excellent translation of a considerable number of the descriptions of disease by foreign writers. The work will be of special value to the large number of readers who take an interest in the history of science, medical and otherwise, but have not the time or the means to consult the original volumes, many of which are difficult of access. The text is liberally interspersed with portraits, facsimile pages and other illustrations.

The Causes of Accidents: Three Lectures on Recent Research into the Causes of Accidents given at the Royal Society of Arts under the Heath Clark Bequest to the National Institute of Industrial Psychology. By Eric Farmer. Pp. vii + 88. (London: Sir Isaac Pitman and Sons, Ltd., 1932.) 3*s.* 6*d.* net.

IN this important little book Mr. Eric Farmer examines critically all the alleged causes of accidents and concludes that, even allowing for chance and for biased liability as factors, there are some people who are inherently more liable to accidents than others. As the people with a high accident rate also tend to have a high sickness rate and to be less efficient, he thinks that these are the people who find modern industrial conditions too great a strain. Accident-prone people should, if possible, be employed in occupations where there is little risk. For this to be effective, careful and detailed records of accidents in various occupations are needed and further research along the lines already started by Mr. Farmer into those personal factors which, the evidence shows, play such an important part.

Physik: ein Lehrbuch für Studierende an den Universitäten und technischen Hochschulen. Von Prof. Wilhelm H. Westphal. Dritte Auflage. Pp. xvi + 596. (Berlin: Julius Springer, 1933.) 19.80 gold marks.

THIS edition is an enlargement of the second, while less important matter has been omitted or compressed. The electrostatic and electromagnetic systems of units are retained, the change to international units having been considered and rejected.

It is a very useful book but somewhat uneven in treatment. For example, thermoelectricity, electrolysis and geometrical optics are less fully treated than electromagnetics, interference and wave theory.

Some parts are very elementary while the more advanced parts such as quantum theory, wave mechanics, etc., are only given in outline. Between these extremes the matter is very good.

The A B C of Chemistry. By J. G. Crowther. Pp. xi + 248. (London: Kegan Paul and Co., Ltd., 1932.) 4*s.* 6*d.* net.

THIS interesting and well-written little book offers a readable summary of some of the broad principles of biochemistry and of the contribution of chemistry to modern civilisation, as is indicated by such chapter headings as "The Breath of Life", "Food", "Vitamins", "Soap", "Dyes" and "Metallurgy". It is accurate in general; but the original synthesis of alcohol is wrongly ascribed to Berthelot, and such obvious misrenderings as "Wolbe", "Erlich", and "Sully" appear in text and index alike. A very generous view is taken of Mayow's contribution to chemistry. The implication (p. 81) that chemical symbols are synonymous with 'jargon' is supererogatory, as is also the prefatory suggestion that teachers of chemistry do not need to make their subject attractive.

Principles of Pharmacy. By Henry B. Mackie. Pp. xi + 281. (London: J. and A. Churchill, 1932.) 10*s.* 6*d.*

THIS is a sound and comprehensive manual which will be found very useful by students of pharmacy. Its scope is indicated by the titles of the main sections: solution, disperse systems, change of state, extraction, enzymes, sterilisation. The book is well illustrated, contains many practical directions, and is provided with a useful bibliography.

The University of London and the Development of Science

THE laying of the foundation stone of the new buildings of the University of London by His Majesty the King on June 26 will mark, in more than one sense, the beginnings of a new chapter in the development of the University. The centenary of the University of London is still distant by some three years, by which time presumably some part of the great new buildings in Bloomsbury should be in occupation, but the years which have passed since its Charter was granted in 1836 have been years of remarkable development. Beginning as an examining body only—a product of the compromise so dear to British Governments—and occupying for the greater part of its existence an anomalous position in the university world, it has during the present century found itself as a great federal university with a huge student population, a great number of distinguished teachers and investigators, and an impressive and growing record of achievement in scholarship and research.

Limited as it was to the duty of examining candidates who presented themselves for its examinations, the University nevertheless gave scientific education a vigorous impulse by according recognition to subjects which, at the best, had hitherto only been regarded as poor relations in the other universities of Great Britain and, at the worst, had been ignored altogether. This is true not only of the well-known Matriculation examination, which had such a profound effect on secondary education in the nineteenth century, but also of the higher examinations of the University. In medicine, for example, from a fairly early stage, great emphasis was laid on the fundamental pre-clinical sciences. It was the first university to establish degrees in science and thus give academic recognition to the science teaching which was being given in London and the provinces.

The strong interest shown by the University in the recognition and advancement of science was no doubt due very largely to the composition of its governing body. This was appointed during a great part of its existence by the Crown and it included a large proportion of fellows of the Royal Society. Among the 'fathers' of 1836 were Airy, Neil Arnott, Beaufort and Faraday, and it is well known that the last-named played a very active part in the affairs of the University. Later there were such famous names as Hooker and Huxley, Lister, Paget and Sharpey; and among its vice-chancellors were Lubbock and Roscoe.

But examinations however well designed and governing bodies however distinguished can only indirectly foster and encourage science and learning. The examining University had (and still has) in the Brown Institution a small institute in which some pioneer research work was carried on. Burden Sanderson, Huxley, Sherrington and Rose Bradford have given lustre to an institution of the existence of which probably few Londoners are aware. In the two great colleges, University and King's, each with a rather longer history than the University in which they were in due course to be incorporated, there were many more leaders in science. University College had from its beginning established chairs in chemistry (the first teaching laboratory in England was opened there in 1828), in geology, botany and zoology. Here, too, were established chairs in anatomy and physiology; and Sharpey, "the founder of modern physiology", sent his two famous pupils Michael Foster to Cambridge and Burden Sanderson to Oxford to spread the new knowledge. In biology, as in chemistry, physics and mathematics, there are again long lists of famous names the mere recital of which would suggest some of the most significant stages in the development of science in the nineteenth century. At King's College there were Lyell, Wheatstone and Daniell; and in those institutions which afterwards were brought together as the Imperial College of Science and Technology were Huxley, Armstrong and Unwin.

Since its reconstitution at the beginning of the twentieth century, when its functions were extended to make it a teaching as well as an examining body, the development and expansion of the University of London, especially in respect of science and medicine, have been on a very large scale. It is only possible here to enumerate some of the happenings of the last crowded years. New courses of study have been planned and new degrees and diplomas instituted. In the colleges, new departments have been called into being and existing departments strengthened, while great institutions such as the London School of Hygiene and Tropical Medicine, devoted primarily to postgraduate work and to research, have started on their course. The building up of a professoriate has been one of the most notable achievements of the University. The number of chairs in all the established physical and biological subjects has been increased and continues to increase, while especially noteworthy is the establishment in the London medical schools of the unit system with full-time directors in medicine, surgery and obstetrics. There are chairs in newer subjects, such as eugenics, genetics, social biology, dietetics, aeronautics, scientific method, chemical engineering and so on, and every academic session sees some addition to their number. The growth in research work fostered by the establishment of research funds and postgraduate scholarships has been not less remarkable. At nearly all the colleges of the University large schemes of rebuilding and extension have been carried out, and the laboratories at institutions such as University College and the Imperial College are among the best in Great Britain or indeed in Europe. The erection of a University Observatory at Hendon is also a notable departure.

It is not easy to predict the lines of future development of the University, but one thing at all events seems obvious. London is, from the nature of things, destined to become more and more a centre of advanced teaching and research. At University College, King's College and the Imperial College, there are teachers and investigators of great distinction, and there are growing up around them important schools of workers in the various branches of science. This is all to the good ; but while the complete severance of teaching from research work would be in many respects unfortunate, there is undoubtedly room for creating more research posts, the occupants of which should be freed from routine teaching. Another direction of advance may be the setting up of special institutions devoted to particular sciences. Either way has much to commend it, but either plan needs very considerable financial resources. Nevertheless, the history of the University of London does not give rise to any fear that the needs of science will be overlooked in the years which lie ahead of it.

Excavations at Tell Duweir, Southern Palestine, 1932–33[*]

THE first season's work of the Wellcome-Colt Archæological Expedition at Tell Duweir in Southern Palestine under the direction of Mr. J. L. Starkey in 1932-33, has amply justified the selection of this site for exploration. It holds out a strong assurance of substantial additions to knowledge of the archæology of southern Palestine in an obscure period at no distant date. Considerable progress has been made in demonstrating the character and relation of the works which converted the Tell into a strongly fortified position ; while the examination of the great stone structure on the summit of the mound, which made Tell Duweir unique as a surface site in Palestine, has been carried to a point which confirms the first impression of its importance.

Before giving an account of the more important results of the excavation, it will not be out of place to mention certain topographical features relating to the Tell. It lies twenty-five miles to the south-west of Jerusalem, twenty-three miles north-east of Gaza, and twenty miles from the sea to the west. The mound, of which the top is 900 ft. above sea level and at a mean height of 130 ft. above ground level, covers 39 acres at its base, while the summit has an area of approximately 22 acres. The average width is 250 metres from east to west and 300 metres from north to south. The remains of a stone revetment, which had encircled the mound, were still to be seen near the summit, while crowning the whole were the imposing remains of the stone buildings, to which reference has already been made.

Tell Duweir has been identified tentatively with Lachish, a strategic strong point of southern Palestine, which offered a strenuous resistance to Joshua, was fortified by Rehoboam, and captured by Sennacherib, and also by Nebuchadnezzar. The siege of the city by the former is depicted on a stone relief from Nineveh which is now in the British Museum. So far, the excavations have produced no positive evidence to confirm the identification, although it may be said that they have added to its probability.

The main points to which investigation was directed during the season's work were the stone revetment, the works at the south-western corner of the mound—a bastion and, it would appear, the main gateway to the city—the city walls, and the building at the top of the mound, which evidently must have been the central structure of the city keep or fortress. A habitation site on the east side of the Tell and another with a cemetery site on the north-west were examined and the latter cleared.

The clearance of the area at the north-west, which provided the greater part of the cultural objects obtained by the excavation—a lengthy operation which continued during the greater part of the time the expedition was at work—came about almost fortuitously. It arose out of the necessary operation of preparing a place for dumping the earth removed from the mound in the course of the work. It was decided to build a retaining wall which would enable the earth to be terraced and made available for future cultivation. In testing bed-rock for the line of the retaining wall, a number of cuttings were found which, on further examination, proved to be a well and rock-chambers or tombs. The well was choked with boulders, but when it had been cleared, a matter of no little difficulty, potsherds from the filling indicated that it was certainly of Middle Bronze age date. The clearance was eventually carried up to the face of the escarpment, which it was found had been cut back until it was nearly vertical, rendering the fortress practically impregnable from this side, while immediately in front of the cliff was a fosse carefully cut in the rock, running north-east and south-west, and following the line of the rock platform on which the mound stands. The fosse was of considerable depth and was only cleared finally by blasting the boulders which formed part of the filling. A cache of pottery with metope pattern with bird, of the type common at Tell el Ajjul, in the lowest levels at a depth of 38 ft. indicated the Middle Bronze age (Hyksos period) as its date.

The tombs first to be examined were found to contain potsherds of Middle or II Iron age date. Many of them had collapsed and had been reused or reroofed in Byzantine times. Both the tombs and the house foundations which lay in the habitation area over the fosse covered a considerable period of time, ranging from Middle Bronze age down even to early Christian times. One tomb can with certainty be attributed to the Hyksos period. House foundations contemporary with the nineteenth dynasty and tombs dating from the eighteenth were discovered.

---

[*] This account of the excavations is based upon the reports of Mr. J. L. Starkey, for access to which we are indebted to Sir Charles Marston. The photographs are by Mr. Ralph Richmond Brown, a member of the Expedition.

In addition to the pottery, the objects recovered from this area included several bronze daggers, bronze toggle pins, bangles, anklets and rings, pottery figurines of Astarte in conventional pose, vases in alabaster and serpentine, beads of various forms and material, seals, and a number of scarabs in steatite, green jasper and carnelian. Some of the steatite examples are of fine workmanship, though of local manufacture. The pottery of certain types affords a link between series found at Jericho and at Tell el Ajjul.

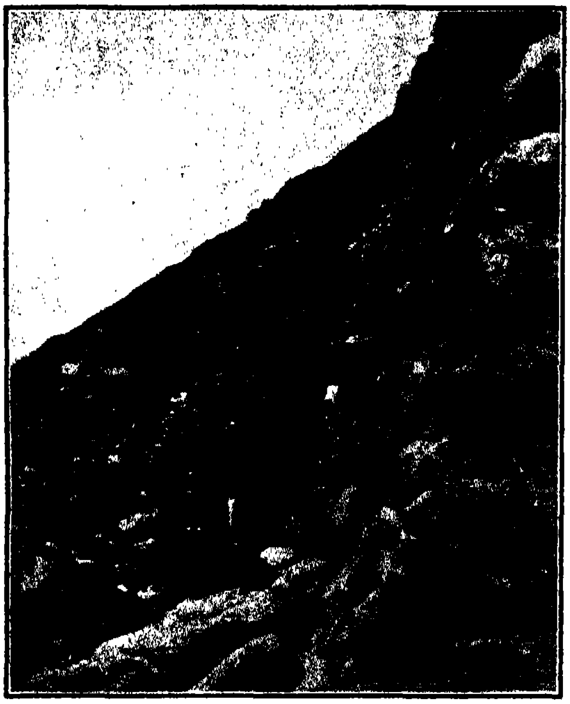

FIG. 1. Section of revetment exposed on north-east side showing stratification of debris. Burnt layer is half-way between boy's head and surface.

The first of the major operations in the examination of the fortress works was the tracing of the line of the stone revetment. This was first cleared at a point at the north-east corner of the Tell, where eleven courses of fine dry-walling, rising to a height of about 20 ft., were uncovered. Further clearances revealed interesting differences in the method of turning the wall at the four corners. At the north-west a bold sweep was supported by five buttresses with their intervening spaces filled with blocks of stone and lime forming a compact mass, a feature unique in Palestinian architecture. There was evidence at the north-east corner (Fig. 1) that this part of the fortress had been subjected to concentrated attack by enemy forces. It was found that the approximate height of the revetment actually preserved encircling the Tell was 16½ ft. and its width 6½ ft.

Within the thickness of the revetment at one point a shaft, some eight feet in diameter, was discovered, which proved to be a well, choked with boulders. This at a depth of 26 ft. cut into living rock. Water level was reached at a depth of 122 ft. and bottom at a depth of 140 ft. from the Tell surface. Immediately behind the revetment enclosing the well were traces of three walls, which probably are the foundations of parts of the internal structure of a tower.

The investigation of the area of the great bastion to the south-west proved to be a problem of considerable intricacy owing to the fact that in the removal of the blocks of stone, the dry-walling offered little guidance in following the line of structure. Eventually it was found that there were three walls running south from the great square tower standing out from the lines of fortification, while a fourth at the highest point represented the city wall. The lowest of the walls, which would appear to be contemporary with the lower revetment and of Israelite age date, was a retaining wall at the side of a ramp which carried the road leading into the city up to the gateway, while a second wall was apparently a flanking wall to the road, here 20–25 ft. wide. Of the two gateways, the left jamb of the outer has disappeared. In the walls flanking the inner gateway are the remains of towers at a distance of approximately forty-four feet apart. Abutting on one of these was a chamber which probably served as a guard room. Two iron lance-heads found nearby lend support to this view, while it was here also that a bronze crest-mount of a helmet was found (Fig. 2). This still showed traces of cloth and leather fastenings and the rivets by which it was affixed to the casque. Its purpose was determined only after some deliberation ; but

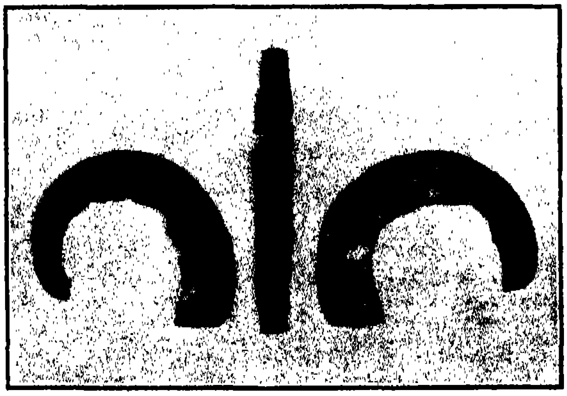

FIG. 2. Bronze crest-mount (two sides) of a helmet, with connecting spacer.

its resemblance to this part of the soldier's helmet as shown in the British Museum relief (Fig. 3) proves its character beyond doubt.

It is of interest to note that the defensive walls, here as elsewhere in the fortress, show that the method of defence was by shallow recessments in the wall rather than by the more usual deep re-entry. This corresponds with the form of defence shown in the British Museum relief.

It is possible to do no more than refer to the interesting habitation site on the eastern side of the Tell, which in the nineteenth dynasty marked the most prosperous period of the city's occupation, and yielded evidence of Egyptian contacts, in order to pass on to the examination of the remains at the summit of the mound. This was undertaken towards the close of the season, but sufficient time was available to reveal that here were the ruins of two structures, of which the earlier had been levelled and used as a platform for the erection of the later building. The ruins of this again had been used later by squatters. It was found that the walls of the later and smaller building, which it may be conjectured was the governor's residency, did not follow the lines of the earlier building, with which its plan had no relation. At north and south the levelled portion of the earlier building projected to form a platform. The residency had contained a large number of public and private rooms and offices with an open courtyard. This latter was probably open to the sky, as it was not filled with limestone blocks as were the spaces representing the other rooms. Some of these blocks showed a curvature which points to a barrel-roofing. The dating of this building is not yet fixed archæologically; but certain considerations point to fourth to fifth century B.C.

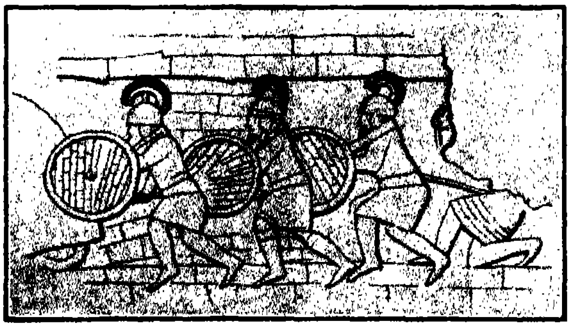

FIG. 3. From bas-relief of the siege of Lachish showing helmets worn by Assyrian soldiers. [*By permission of the Trustees of the British Museum.*]

Two further problems arising out of the excavation remain to be mentioned. These, it is perhaps not unfair to say, constitute the main contributions of the season's work to the discussion of the historical question raised by Tell Duweir. In examining the defensive works of the fortress and in removing the earth from the face of the revetment, evidence was found that the walls had been breached in two, or possibly three, attacks. The breaches had been repaired, although usually with little skill or care; but the defences had afterwards been subjected to the effects of a serious conflagration. In the stratification, this conflagration was represented by a stratum consisting of calcined limestone and charcoal in which were the remains of tree trunks of considerable size. It is suggested that earlier breaches in the defences were made during the siege by Sennacherib, dated tentatively at 701 B.C., while the evidence of conflagration bears witness to the more thoroughgoing methods of the army of Nebuchadnezzar in 586 B.C., which, cutting down the trees on the neighbouring hills and in the olive groves, piled the trunks against the walls and set fire to them, utterly destroying the city's defences in its lines of attack.

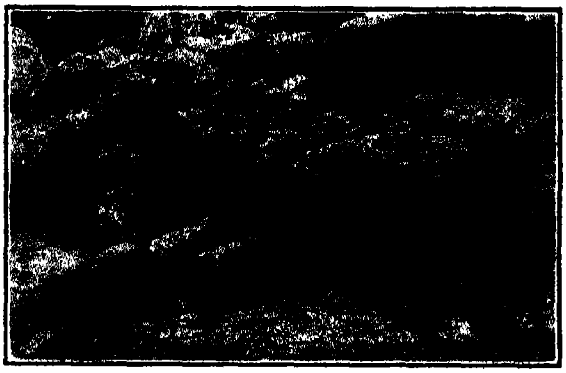

FIG. 4. West wall of residency lavatory and bathroom, showing sanitary fitting and, on left, drain from bath room.

Attention was directed to the second problem in the course of the excavation by the occurrence of burnt brick in the debris at various points, as well as by traces of burnt brick building in the area of the well in the revetment to which reference has been made above. The problem was resolved up to a point by a section through the city walls near the bastion, where it was found that an earlier system of walls constructed of unbaked mud brick lay on a foundation of stone below the late city walls. The width of the walls, 19 ft., points to their substantial character.

It remains only to mention briefly the result of a complete section taken down to bed rock through a depth of 38 ft. of deposits. This section showed that the deposits of the lowest 10 ft. belonged to early Palestinian culture; and it provided a complete and unbroken series of potsherds from the third millennium B.C. down to the close of the city's occupation. Among the early wares are examples of the almost unknown black burnish ware, hitherto discovered only in the Jordan valley, which shows resemblances to the ware of predynastic Egypt produced by the muffled technique. For this Tell Duweir now affords a new southern limit of distribution in Palestine.

An exhibition of the antiquities found during the excavations will be held in London during July.

Problems of British Forestry

IN a lecture to the British Science Guild at its annual general meeting held in the Mansion House, London, on June 19, Prof. R. S. Troup discussed the important question of forestry in Great Britain, with special reference to the programme of State afforestation now being carried out by the Forestry Commission, its progress to date, its limitations, and some of the scientific and technical problems following in its train ; he also reviewed the question of private forestry and pointed out some of its defects. The significance of British forestry at the present time may be realised from the fact that less than five per cent of the requirements of Great Britain in timber are met from home-grown sources, that the forest capital of the world is being consumed at an alarming rate, and that the shortage of timber which is likely to result may cause much distress in the absence of a supply of home-grown timber.

Dealing with the planting scheme of the Forestry Commission, Prof. Troup explained that the afforestation of large tracts of bare land with species which are in many cases exotic, introduces problems of a complicated nature ; these are investigated by a special research branch of the Forestry Commission aided by certain universities and particularly by the Imperial Forestry Institute at Oxford. Among these problems, not the least important are those relating to soil conditions, such, for example, as are met with on the heath lands which form a considerable portion of the area available for forestry : on such lands the soil tends to become degraded owing to the leaching out of the soil nutrients in a climate where precipitation exceeds evaporation, with the result that the establishment of tree-growth is often difficult. In such cases deep ploughing has proved successful on an experimental scale. On peat lands good results have been obtained by draining and planting on square turfs dug out of the drains and placed in an inverted position on the surface of the ground ; by this means the turf becomes oxidised and breaks down, liberating nitrogen and other essential nutrients. Experiments in the use of basic slag have given remarkable results on very unfavourable peat soils.

Research in Great Britain on the control of pests and diseases is mainly centralised at the Imperial Forestry Institute at Oxford. In forestry, direct measures for the control of insect pests, such as trapping, grease-banding, and hand-collection may prove too costly, and special attention has to be directed towards preventive measures of a sylvicultural character, such as the avoidance of large areas of pure crops, the removal of sickly trees forming breeding centres for noxious insects, and the barking of newly-felled coniferous trees in order to prevent the multiplication of destructive beetles which lay eggs in their bark.

Increased attention is being directed to methods of biological control for dealing with forest insect pests. In this connexion, an interesting study has recently been made of the life histories of the *Sirex* woodwasps which bore into living coniferous trees, and of their parasites, the large ichneumonid, *Rhyssa persuasoria*, and the smaller cynipoid, *Ibalia leucospoides*. As a result of this work, larvæ of the *Rhyssa* parasite have been exported in numbers to New Zealand by the Parasite Laboratory at Farnham Royal in an attempt to deal with an epidemic of woodwasps in the coniferous plantations there. Similar studies are being made of the parasites of the pine bark-beetle, *Myelophilus piniperda*, and the oak leaf roller moth, *Tortrix viridana*, which causes extensive defoliation and mortality among oak trees.

With regard to fungal and bacterial diseases, important work is being carried out on predisposing causes, among which frost promises to be of more importance than has hitherto been suspected. The oak rot disease caused by the fungus *Stereum spadiceum*, which has resulted in extensive loss in the Forest of Dean, furnishes an example of the complicated character of some of these predisposing causes. Investigations carried out so far indicate that the ingress of this fungus is due in part to the fact that, in the days of wooden ships, oak trees were widely spaced to encourage the growth of large branches for the production of curved shipbuilding timber. Later, when wooden ships were abandoned and the value of the trees lay in the bole rather than in the branches, the oaks were left to crowd each other. The lower branches thus died off, and through the dead wood the fungus gained admission to the interior of the bole, causing its decay.

The progress made so far in carrying out the State afforestation programme in Great Britain has been good, but in Prof. Troup's opinion the programme itself needs reconsideration, since it was formulated during the War, and is based primarily on questions of national security. During the years following the War, other weighty factors have forced themselves into prominence, including the prospect of a world shortage of timber and the question of unemployment. The time has now arrived, therefore, when the forest policy of Britain should be reconsidered on a wider basis. Private forestry is in an unsatisfactory state, a large percentage of the private woodlands being unproductive to a greater or less extent, while scientific forest management is the exception rather than the rule. This is probably due in some measure to the fact that most of our woodland estates are too small to form economic units : a possible remedy would be to work on a co-operative basis with trained forest managers in charge of groups of estates. Legislation may even be necessary, as in the case of certain Continental countries, to provide for the management of private woodlands on approved lines and the compulsory reafforestation of felled areas.

Obituary

SIR ERNEST MOIR, BT.

WE regret to record the death, which occurred on June 14, at the age of seventy-one years, of Sir Ernest William Moir. Born on June 9, 1862, Moir in the early part of his career came into close contact with Fowler, Baker, Arrol, Wolfe-Barry and other eminent civil engineers and during his long and distinguished career as a partner in the firm of Messrs. S. Pearson and Son, Limited, worthily upheld the high traditions of those who, as contractors, are responsible for carrying out works of the greatest magnitude. Both in his presidential address on "Engineering Difficulties" to the Junior Institution of Engineers in December, 1929, and his address entitled "The Interdependence of Science and Engineering, with some Examples", given as president of Section G (Engineering) at the Bristol meeting of the British Association in 1930, he made many interesting references to some of the important undertakings with which he had been associated; and as "the first contracting civil engineer who has been honoured by the British Association", at Bristol he appropriately dealt at considerable length with the economics of engineering construction. Another section of his address was devoted to the bacteriological and entomological sciences and their influence on civil engineering.

Educated first at University College School, and then at University College, London, where he studied under Kennedy and Vernon Harcourt, Moir began his practical training in the yards and shops of Messrs. R. Napier and Sons, Glasgow, of which Dr. A. C. Kirk was the manager. His first important task was the building and launching of the large caissons for the foundations of the Forth Bridge. Joining the staff of Messrs. Tancred, Arrol and Co., he was employed on the construction of the south cantilevers of the bridge and then through Sir Benjamin Baker was sent in 1889 to New York to assist in the completion of the Hudson River (North) Tunnel which had been started in 1874, only to be abandoned in 1888. It was in connexion with the work on this tunnel that he introduced the use of recompression chambers for men working in compressed air. The use of this medical air lock reduced the death-rate among the staff, which in 1890 had been 25 per cent per annum, to 1½ per cent.

By this time, Moir had become a member of the firm of Messrs. S. Pearson and Son, of which the late Lord Cowdray (1856–1927) was long the head, and as such he was responsible for the construction of the Blackwall Tunnel beneath the Thames, a difficult piece of work successfully completed in 1897. Afterwards, Moir was connected with the construction of the four railway tunnels under the East River from New York to Long Island and with harbour work at Seaham, Dover and elsewhere. His latest important undertaking was the construction of the great breakwater at Valparaiso, founded in 187 ft. of water. The base of this breakwater consists of a huge bank of deposited sand, while the upper part of the structure is composed of 60-ton concrete blocks interlocked with each other. An account of this work was given to the Institution of Civil Engineers in December, 1931, by Mr. W. F. Stanton.

Appointed a member of the Admiralty Engineering Committee in 1912, from 1916 until 1919 Moir held important positions under the Ministry of Munitions and in 1924–25 was chairman of the Government Committee on New Methods of House Building. He was made a baronet in 1916 and is now succeeded in the title by his younger son, Capt. Arrol Moir.

News and Views

Prof. Manne Siegbahn

AT a meeting of the Physical Society held on June 16 the tenth Duddell medal was presented to Prof. Wolfgang Gaede (see NATURE of Feb. 11, p. 195). The presentation was followed by the delivery of the eighteenth Guthrie lecture by Prof. Manne Siegbahn, professor of general physics in the University of Uppsala, on "Studies in the Extreme Ultra-Violet and the Very Soft X-Ray Region". It is largely due to Prof. Siegbahn's technical and experimental skill, backed by a wide knowledge of physical science, that our present acquaintance with atomic structure has made such remarkable progress. In 1912, von Laue first gave experimental proof that the X-rays resembled light in all respects except that the lengths of their ether waves were many thousands of times shorter. His method was based upon the supposition that the ordered array of the atoms in a crystal would act upon X-rays just as, in familiar ways, a grosser array of particles or lines or obstructions of any kind act upon the longer waves of light, so causing such phenomena as the halo round the moon, or the colours of mother of pearl, or the iridescence of wings and wing cases of certain insects. The successful experiment at once opened the way to two separate lines of research, both of which have been rich in results. The first has led to our rapidly growing knowledge of the crystalline state of matter, including the bodies which are crystals *par excellence*. The other was first followed by Moseley and Darwin, who employed the new methods in the investigation of the X-rays themselves.

IT was then that Siegbahn, following the same line of research, began his investigations. He effected improvements in the design and construction of apparatus for measuring the wave-lengths of X-rays which have endowed them with an accuracy comparable with the corresponding optical instruments. It is amazing to look back over the last twenty years to the experiments with which this work began, and to compare their crudity, which nevertheless could not hide their obvious importance or the magnificence of their promise, with the finish of to-day. It is largely to Prof. Siegbahn that we owe the modern precision, and the fulfilment of that promise. His extremely accurate measurements of the lengths of the waves which the various atoms emit, serve as definite indications of their internal structure, and every improvement has brought new and valuable information. Not often has refinement of instrumental design and use brought such a plentiful and immediate harvest. It is interesting to note that it was Ångstrom, also a Swede, who first realised the accuracy in optical measurements which necessitated the choice of a special unit of length for their description. Ångstrom himself measured the lengths of waves of light and found them to be a few thousand of his units: the wave-lengths of X-rays are of the order of a single unit.

Dr. Michael Polanyi

DR. MICHAEL POLANYI has accepted a chair of physical chemistry in the University of Manchester, and will take up the post at the beginning of the next session. Dr. Polanyi, who is a Hungarian by birth, studied medicine in the University of Budapest and chemistry in the Technical High School of Karlsruhe. After service as surgeon with the Austrian forces during the War, he became assistant to Prof. Hevessy, professor of theoretical chemistry at the University of Budapest. In 1919 he returned to Karlsruhe, since when he has held posts in the Kaiser-Wilhelm Institute for Textile Chemistry, the Technical High School in Berlin, and the Kaiser-Wilhelm Institute for Physical and Electro-chemistry. Dr. Polanyi is a well-known physical chemist. His first notable research was a theory of adsorption, published in 1917; he has also made discoveries in connexion with the structure of cellulose and the mechanical properties of metals and other solids. His present investigations relate to the theoretical and experimental study of reaction kinetics and the mechanism of chemical reactions. It is this line of research which, it is anticipated, he will pursue in Manchester.

Johann Jacob Scheuchzer, 1672–1733

THOUGH as a science, the birth of geology dates only from the latter part of the eighteenth century, prior to that many men had been interested in the study of rocks and fossils and had recorded valuable observations. Among these men was the Swiss doctor, Johann Jacob Scheuchzer, the bicentenary of whose death occurs on June 25. Born at Zurich on August 4, 1672, Scheuchzer qualified as a doctor at Utrecht and paid some attention to mathematics. For many years he held a professorship in his native city. His main interest, however, was in natural history and especially in fossils and minerals. He translated Woodward's "Natural History of the Earth" into Latin and published several works of his own. Included in these was his "Itinera per Helvetiæ Alpinas Regiones" (1702–11), in which for the first time glaciers are mentioned as a subject for scientific investigation. He gave careful descriptions of several glaciers he had visited and explained their movement as a result of the infiltration and freezing of water in cracks and other spaces. He was thus the founder of the theory of dilatation, afterwards advocated by Charpentier and Agassiz. His natural history of Switzerland contains a special chapter dealing with what Scheuchzer thought were fossils left by the Great Deluge, and towards the close of his life he thought he had discovered in the beds at Oeningen, between Constance and Schaffhausen, the skeleton of one of the "infamous men whose sins brought upon the world the dire misfortune". But the supposed *Homo diluvii* was afterwards shown by Cuvier to be a reptile and it was called *Andrias Scheuchzeri* in honour of its discoverer. The specimen was presented to the Teyler Museum at Haarlem.

Vivisection of Criminals

THE BISHOP OF DURHAM set the ball of controversy rolling when he delivered the eighth Fison memorial lecture on June 15 at Guy's Hospital on "Ethical Conditions of Scientific Method". After discussing the case for and against vivisection of animals, he submitted the question whether in no case might man be subjected to vivisection in the interest of science. Dr. Henson asked if there was any objection to the vivisection of criminals who, by the law of their country, had been condemned to death. In their case, the issue of inherent rights could not be raised, for these had already been cancelled, and they were dealt with penally on this hypothesis. Why should not the punishment of a criminal take a form which was serviceable to the community? Why should he not at least be given the opportunity of making in this way some atonement for his sins against society? At present, deductions drawn from the responses of the anthropoid apes or even dogs have to suffice, where direct experiment on man would present a speedier route to knowledge. This applies to human physiology, especially of the nervous and digestive systems and in a lesser degree to pathology as regards infectivity and immunity. There is, of course, the possible difficulty to be encountered in finding an experimenter, at any rate in England, who would impose conditions which might not meet with the penal requirements. In any event, the subject bristles with difficulties the discussion of which would take up more space than is available in these columns.

International Ornithological Congress

THE eighth International Ornithological Congress is to be held at the University of Oxford in July 1934, under the presidency of Dr. E. Stresemann, of Berlin. The International Ornithological Congress was originally held every five years, but at the last Congress, at Amsterdam in 1930, when the president was Dr. E. Lönnberg of Sweden, it was decided to hold it every four years. The last meeting of the Ornithological Congress in England was at the Imperial Institute, London, in 1905, with Dr. R. B. Sharpe as president. In 1910 it was held in Berlin, and it was proposed to hold the 1915 Congress at Sarajevo, Yugoslavia, but in the meantime the War broke out and no further Congress was held until 1926, when, mainly through the efforts of Dr. Ernst Hartet, keeper at Tring Museum, it was resumed at Copenhagen. Preliminary arrangements have already been made for the 1934 Congress at Oxford, and the Rev. F. C. R. Jourdain, of the British Ornithologists' Union, has been elected honorary secretary. Dr. P. R. Lowe, of the British Museum, has been elected chairman of the executive committee, which includes Lord Rothschild, Lord Scone, Dr. C. B. Ticehurst, Dr. Sclater, and Messrs. Stuart-Baker and H. F. Witherby, president of the British Ornithologists' Union.

Delegates to the Congress will include the leading ornithologists from all parts of the world, particularly Australia, New Zealand, Argentina, Brazil, Japan, India, the United States, Canada, and all European countries. The problem of oil pollution of the sea, whereby hundreds of sea-birds, including many rare species, are annually being destroyed especially on the North Atlantic shores, will be a prominent feature of the section on bird protection, while the practice of 'ringing' as a means of tracing bird migrations will also be discussed. One of the most important items, however, is the project for founding an Institute of Ornithology at the University of Oxford, which it is hoped to develop out of the existing scheme of research in economic ornithology at Oxford, the grant for which expires in September, 1933. The new institute is intended to be a national centre for field ornithologists as the British Museum is for systematists. £8,000 is needed to run the Institute for a preliminary five years while steps are being taken to put it on a more permanent basis. An appeal will be made not only for funds but also for gifts of books, field notes and photographs, etc., for equipping it. It is also proposed to arrange at least one long excursion to study British bird life, and South Wales will probably be chosen as the area to visit though several shorter excursions are to be made. The lectures and papers are to be given in English, French, German and Italian.

New Buildings of the University of London

Under the title "The New Buildings for the University of London" (The Dryden Press) Mr. T. Ll. Humberstone has published a 'symposium', in which a contribution to Nature (July 9, 1932; p. 49) is reprinted, followed by an explanation of the plan of the proposed buildings by the architect (illustrated), and expressions of opinion from architects and laymen and a supplementary note by Mr. Humberstone himself. It will be remembered that Mr. Humberstone in his original article, after a brief summary of past difficulties and controversy connected with the accommodation of the University, expressed certain misgivings in regard to the suitability of the proposed buildings, especially in relation to the provision for scientific research. These views are now supplemented by critical comments from others. Prof. S. D. Adshead, professor of town planning in the University, for example, remarks that "if only on account of its rigidity—the system must fail". In his supplementary note, Mr. Humberstone reverts to his previous contention that the University buildings should make provision for an institute for scientific research, pointing out the unsuitability of the scheme, as well as the unnecessary expense involved, for the purpose, and discusses the bearing of the conception of the University as a federation upon the development of facilities for research as part of the equipment and organisation of the University, as distinct from its constituent colleges.

San Diego Museum

Local patriotism flourishes perennially in the United States. As part of a campaign "Know your San Diego", Mr. Malcom J. Rogers, curator in anthropology in the Museum of San Diego, has recently broadcast a lecture, in which he gave an account of the origin and growth of the collections. The nucleus of the museum was an exhibit at the Panama-California Exposition of 1915–16. The organisers of the exhibition, in consultation with officials of the U.S. National Museum, spent some three years in getting together a collection to illustrate the origin, racial types and culture of man. Expeditions were sent to Asia, Africa, South America, the Pacific and the Arctic for material and the collections then made were housed in the only permanent building in the exhibition, the California Quadrangle, which is still its name, as it had been intended from the first that what, it was hoped, would be a unique educational exhibit, should "not be a thing for the moment, but an enduring institution for the benefit of the people of San Diego and its visitors". At the close of the exhibition the collections were transferred to a permanent Museum Association in trust for the people of San Diego. Dr. Edgar L. Hewett, of the Archæological Institute of America, who had been responsible for this department during the exhibition, was made the first director of the Museum. Constant additions have been made to the collections, which are now so extensive that it is possible only to show the exhibits in rotation. They are arranged departmentally, to illustrate man's origin (by casts), physical types, and culture in the past and present. The archæology of Central America and the Mayas is abundantly illustrated, the most striking and best-known buildings and monuments being represented by replicas. The pride of the Museum, however, is the collection from the south-western States and, more particularly, that from Southern California, the latter being unique and beyond question the most complete in existence.

Bird Life on Ailsa Craig

A report on bird life on Ailsa Craig was submitted to Ayr County Council on May 30, the Earl of Glasgow presiding, following a communication from the

Scottish Office. The report, prepared by Lieut.-Commdr. G. H. Hughes-Onslow, Barr, and Mr. T. Smith, Maybole, recommended that protection be given to guillemots, razor-bills, puffins, kittiwake gulls, and oyster catchers, and also to black guillemots, stormy petrels and fulmar petrels, which have been observed in pairs on the Craig but have not yet nested there, although they have nested on the neighbouring mainland. Protection was not recommended for solan geese or gannets, the stock of which is sufficiently large, nor for the greater black-backed gulls, lesser black-backed gulls, herring gulls, and cormorants, which are so numerous all around our coasts and so destructive to fish and other life as not to merit protection. Regarding the practice of shooting birds from boats, the reporters agreed with the Secretary of State for Scotland that prohibition could not be enforced. The practice, however, should be discouraged. The comparatively few eggs collected by the tenants on the island has no effect on the bird life. The report was adopted for submission to the Scottish Office.

Peterhead Sealers and Whalers

IN the January-February number of the *Scottish Naturalist*, No. 199, 1933, Dr. Robert W. Gray continues his very interesting account of "Peterhead Sealers and Whalers: A Contribution to the History of the Whaling Industry", begun in 1932 (September-October). Peterhead first sent a whaling vessel to the Greenland Sea (the "Greenland" of the old sealers and whalers, the Spitsbergen Sea, the ocean between Greenland and Spitsbergen) in 1788, and a Greenland whaling ship sailed out of Peterhead for the last time in 1893. Dr. Gray, whose grandfather and father both commanded whaling ships, possesses original log-books containing a large amount of reliable information as to the whaling in the latter portion of this period and has gathered together data from many sources relating to the earlier years, beginning with the tiny *Robert*, the pioneer vessel. Up to the year 1814 the fishery had been pursued generally in the more northerly regions, but after this the boats began to explore southwards. From 1825 the Peterhead ships went mostly to the Davis Straits and the whales of the Greenland sea were left alone for a time. In 1837 the whalers returned to the north and both northern and southern fishing was continued, the northern fishery in some years proving very successful. A great deal is to be learned by reading this article, the present portion going up to the year 1874. In that year, according to the log-book of the *Eclipse* it was an open season, northerly winds prevailed in April, May and June, there was a strong south-westerly drift and the edge of the ice lay far west. The ice was drifting south at the rate of twenty to thirty miles a day, and at the end of the voyage it was estimated that more than 300,000 square miles of ice drifted south out of the Arctic Ocean in three months.

Electrical and Rubber Equipment on the Farm

THE supply of electricity to rural areas is continually extending so that increasing numbers of farmers are interested in this alternative method of lighting their farm buildings and conducting power operations in and around the homestead. In these circumstances a visit to a farm carrying a good equipment of the ordinary machinery as well as a complete electrical installation gives an excellent view of the possibilities. At Rothamsted, a thoroughly up-to-date electrical equipment has been supplied by the General Electrical Co., Ltd., and means are provided for making exact comparisons of electricity and oil as sources of power for farm operations. On June 19 a demonstration of the plant was arranged for a party of experts and farmers. The visitors were conducted round the farm buildings and examined a large number of power operations in progress, the motors ranging from 20 h.p. down to ½ h.p. according to the nature of the work. A very complete and efficient lighting system was demonstrated and electricity was in use for water heating, sterilising, and various other stationary processes. First-hand information with regard to the engineering details and performance of the machinery was also available. A demonstration of a number of uses of rubber on the farm was arranged by the Dunlop Rubber Co., Ltd. Various types of rubber flooring for stables, cowsheds and piggeries were on view. The visitors also examined the performance of heavily laden farm carts equipped with low-pressure rubber tyres and rubber-tyred tractors at work on the arable land.

Scottish Marine Biological Station, Millport

THE Scottish Marine Biological Association's annual report on the work of its laboratory at Millport on the Firth of Clyde, for the year 1931–32, has recently been issued (Glasgow: 185 St. Vincent Street). The Association is to be congratulated on the large measure of success which is attending the important though highly specialised researches upon which its small staff of four is actively engaged. Their work has received high commendation from H.M. Development Commissioners and other interested organisations well qualified to assess its value. Over and above the important work on *Calanus finmarchicus* (see NATURE of June 10, p. 843) which is being done, the results of a considerable number of other researches carried out by the station staff and visiting workers have been published in the course of the year. Chief among these must be mentioned several important memoirs by Miss Marshall, Mr. Orr, and Dr. Nicholls, embodying the results of their researches while members of the Australian Great Barrier Reef Expedition of 1928–29. In common with all other organisations in Great Britain and other countries, the Millport Laboratory has been adversely affected by the present economic depression. The block grant originally voted to it by H.M. Treasury—on condition that a proportional sum be raised independently from other sources—was considerably cut down, and the local contributions fell short of the required amount by fully £100. It is greatly to be hoped that the state of financial stringency which still exists will not be allowed unduly to restrict the activities of this and similar institutions.

Institution of Electrical Engineers' Wiring Regulations

THE booklet on "Regulations for the Electrical Equipment of Buildings" (price 1*s.* net) published by the Institution of Electrical Engineers has proved a great boon to the industry. It replaces many rules and regulations published by supply companies and insurance companies. The ninth edition was published in May 1927 and the tenth edition is in active preparation. The new edition will contain rules relating to electric signs and to the new luminous discharge tube installations. These new rules have been approved by the representatives of those interested and by the Council of the Institution of Electrical Engineers. They deal very thoroughly with possible risks of fire and the precautions necessary to avoid risk of shock. These rules are now issued in advance of the tenth edition in a supplementary booklet. Copies of this supplement can be obtained free of charge, for insertion in existing copies of the Regulations, on application to the Secretary of the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2.

Home-Grown Timber in Great Britain, 1930

THE Forestry Commission has issued a small pamphlet on home-grown timber (Report on Census of Production of Home-Grown Timber, 1930. H.M. Stationery Office. Dec. 30, 1932). The object of the pamphlet is to contrast the production or utilisation of timber in Great Britain in 1930 with the amount used in 1924. With this object, schedules were issued to woodland owners who had furnished returns in 1924. The census shows that there has been a falling-off between 1924 and 1930, both in respect of the volume and value of the material produced. As regards volume, there is a difference of 14 per cent, the decline being from 55,985,000 cub. ft. in 1924 to 48,057,000 cub. ft. in 1930. The value of the material utilised has fallen in the same period from £2,036,000 to £1,545,000, representing a reduction of nearly 12 per cent. Prices ruled higher in England than in Scotland or Wales, but were certainly low as a whole, especially for the fine hardwoods such as oak (16*d.* per cub. foot in England with an average for Great Britain of 15*d.*; and 22½*d.* for ash in England with an average of 21*d.* for Great Britain—both for timber of saw-mill size). A little more than one-fourth of the total volume of material produced during 1930 consisted of the three fine hardwoods, oak, beech and ash (a total of 12,934,700 cub. ft.) and the figures demonstrate that the bulk of the fellings of these three valuable species were made in England, where 8,120,900 cub. ft. (out of the 12,934,700 cub. ft.) were cut, of which 6,194,200 cub. ft. were oak. Some of the fellings being made in these English woodlands are of the worst lumbering type—unchecked clear-felling and disposal of all that is saleable, the area being left clogged with rubbish and in a most unsightly state. It may be suggested that the time has arrived when a law prohibiting this type of unchecked lumbering, which has done such extensive harm to forest tracts throughout the globe, is urgently needed.

Cultivated Oaks

SIR OSCAR WARBURG and Mr. E. F. Warburg have published details of the oaks in cultivation in Sir Oscar's garden at Headley, Epsom, and elsewhere in the British Isles ("Oaks in Cultivation in the British Isles", *J. Roy. Hort. Soc.*, **58**, Pt. 1, pp. 176–189, Feb. 1933). The account is copiously illustrated with many clear photographs of herbarium specimens and the various species of the genera *Lithocarpus* and *Quercus*, which all come under the general category of 'oaks', are described in detail. Three sub-genera of *Quercus* are recognised—*Cyclobalanopsis*, *Erythrobalanus* and *Lepidobalanus*. A useful list at the end of the article sets forth the common name, the group and the area of origin in non-technical, as well as in botanical, language. Several notes on some South American oaks and garden forms help to clear up difficulties of classification, and a fairly extensive bibliography is added.

A Polish Guide to Zoology

THE Polish Institute for the Promotion of Science and Letters is publishing a "Handbook for Self-Education" (Poradnik dla Samoúkow) under the general editorship of Prof. S. Michalski, and vol. 10 (554 pages), dealing with histology, animal physiology, embryology and comparative animal psychology, has just been issued (Warszawa. Imienia Mianowskiego. 18 zlotys). This is the second section on zoology and contains contributions from Profs. Maziarski, Bialisewicz and Godlewski, whilst Miss Bohn-Drzewina's article on animal psychology, originally written in 1929, is very fittingly appended. The object of this publication is to guide students (and lecturers) in their reading and to direct attention to general principles, to the historical developments and especially to the literature of each branch of the subject. It is not intended to supplant any of the standard textbooks but to supplement them. It is noticeable that the authors are most familiar with German treatises on the various branches of zoology under consideration, but some French and, more rarely, English works are cited and listed in the bibliographies. The work will prove useful to those Polish students who, for any reason, do not enjoy close contact with their lecturers, and it has apparently been compiled with that object in mind.

Veterinary Research in the Union of South Africa

THE eighteenth report of the Director of Veterinary Services and Animal Industry, Onderstepoort, Pretoria, contains matter of value to the veterinarian and agriculturist. Several papers deal with parasitic and virus diseases of animals, and considerable space is devoted to the subjects of mineral deficiency and metabolism and to plants poisonous to stock. Mr. Bedford contributes an exhaustive synoptic check-list and host-list of ectoparasites found on South African mammals, birds, and reptiles, and Mr. Steyn has continued his observations on the effect of sulphur on merino sheep. A ration of 5 gm. of sulphur thrice weekly improves the condition of the sheep and increases the wool yield from an average of 8·4 lb. to an average of 11·625 lb. It also increases resistance to prussic acid, and may be of value in reducing 'geilsiekte', a poisoning that arises from ingestion of certain plants in which a cyanogenetic glycoside is present. The report, in two parts, is admirably produced and illustrated (Government Printer, Pretoria, 20*s.*)

Health of the Navy during 1931

The statistical report of the health of the Navy for the year 1931, by the Medical Director General, Vice-Adm. R. St. G. S. Bond, states that there was an increase in the incidence of disease as compared with the five years' average and with 1930, largely due to an increase in influenza of nearly 2,000 cases. Malaria and venereal diseases declined markedly. Nine cases of undulant fever were reported from the Mediterranean station. It is remarked that undulant fever has increased among Maltese civilians, and in consequence a Government commission is considering the possibility of introducing the compulsory pasteurisation of goats' milk at a central distributing station and the prohibition of retail sales as at present transacted by driving the goats from door to door. Only five cases of enteric fevers were reported.

Index Veterinarius

The first number of the *Index Veterinarius*, covering the indexing done at the Imperial Bureau of Animal Health during the first quarter of 1933, will be issued during the summer. This work will be a complete index to publications relating to veterinary research and public health administration and education. An annual volume, which will be in crown quarto size, will run to about 1,600 pages; and a number, consisting of about 400 pages, will be issued each quarter. About 10,000 references will be indexed each year, each reference being suitably cross-indexed alphabetically both under the names of authors and subjects and, with cross-indexing, there will be about 50,000 insertions in a volume. The price of the *Index* is £4 a volume (four quarterly issues) including postage. Orders should be sent to the Imperial Bureau of Animal Health, Veterinary Laboratory, Ministry of Agriculture and Fisheries, Weybridge, Surrey, England.

Library of the London School of Hygiene and Tropical Medicine

The London School of Hygiene and Tropical Medicine has issued a second edition, compiled by the librarian, Mr. Cyril Barnard, of the "Hand List of Periodicals" contained in the Library on January 31, 1933 (Wightman and Co., Ltd., Dugdale Street, S.E.5. 1*s.* 3*d.*). The arrangement of entries is alphabetical by titles, according to the rules adopted in the "World List", and the "World List" numbers are added to all the periodicals which are contained in that publication. An index of societies and institutions is appended, with the number in the list of the periodicals attached to each entry.

Service for the Blind

The Report of the Librarian of Congress for 1932 witnesses to the effort being made to meet the needs of blind readers in the United States. The number of blind readers who borrowed embossed material during the year was 3,225, and the library collection now contains 24,824 items. An attempt is made to furnish blind readers with the best literature in all fields of knowledge which, on account of the financially unprofitable nature of embossed printing, they have hitherto been unable to obtain. The type of book suitable for transcription is limited, since works the value or attractiveness of which rests largely upon illustrations, are barred. But within the limits, the special accessions, which began with Woodrow Wilson's "George Washington" and contain, on the scientific side, works by Jeans, Maeterlinck, Arthur Keith, Harvey-Gibson, Russell and others, make a notable list of 126 works in Braille and 31 in Moon type.

Preservation of Metallic Objects in Museums

Museum curators are often faced and baffled by the problem of dealing with objects of metal which have deteriorated through exposure, and tend to go from bad to worse when placed on exhibition. They will find a very useful guide to the most satisfactory methods of treatment in a paper by Dr. Alexander Scott in the *Museums Journal* of April (p. 4), where, in addition, hints are given for making brittle substances flexible, for using hydrogen peroxide in restoring degraded flake white to its original colour, for treating foxed prints and removing oil stains.

Collection and Preservation of Animals

The National Museum of Canada has just published a work on "Methods of Collecting and Preserving Vertebrate Animals", which ought to prove useful to travellers and holiday-makers who wish to add to their pleasures that of contributing to the knowledge of their country's fauna (Nat. Mus. Canada, Bulletin No. 69, Biological Series, No. 18, Ottawa, 1932). While less compact and less convenient in size for carrying than the well-known British Museum collectors' handbooks, Mr. R. M. Anderson's book has the advantage of being more thorough in its treatment and of containing a large number of illustrations showing steps in the progress of skinning. In separate chapters it deals with the collecting and skinning of mammals, birds, reptiles, amphibians and fishes, and a special chapter describes the collecting of skeletons. There are 135 pages of descriptive matter, a very complete index of 5 pages, 46 illustrations, and the cost is only 25 cents.

The late Lieut.-Col. A. W. Alcock

In connexion with the obituary notice of the late Lieut.-Col. A. W. Alcock in Nature of April 22, Dr. B. Prashad, of the Zoological Survey of India, states that Col. Alcock's association with the Indian Museum began at the end of the survey season of 1888–89, for with the beginning of the south-west monsoon the surgeon-naturalist used to come every year for the recess period to the Indian Museum, to work out his collections. During the four years of his appointment as the surgeon-naturalist, Alcock spent every recess season in the Indian Museum, and it was during this time and as a result of his association with J. Wood-Mason, then superintendent of the Indian Museum, that Alcock developed his interest in Crustacea. In April 1893, Alcock was appointed officiating superintendent of the Indian Museum, and was confirmed in this appointment in May on the death of Wood-Mason; he held the appointment as professor of zoology in the Medical College of Calcutta as a subsidiary charge. The dates given in the obituary in NATURE, which differ slightly from those quoted by Dr. Prashad, were taken from Col. Alcock's own diary.

Announcements

PROF. R. G. HARRISON, professor of comparative anatomy at Yale University, will deliver the Croonian lecture before the Royal Society on June 29, at 4.30. The title of Prof. Harrison's lecture will be: "The Origin and Development of the Nervous System studied by the Methods of Experimental Embryology".

MR. K. S. KRISHNAN, reader in physics in the University of Dacca, has been elected secretary of the Indian Association for the Cultivation of Science, 210 Bow Bazar Street, Calcutta, in succession to Sir C. V. Raman. Mr. Krishnan has also been appointed the Mahendralal Sircar research professor in physics of the Association.

THE Medical Research Council, acting for the Rockefeller Foundation, has awarded travelling fellowships for the academic year 1933–34 to the following: Mr. H. W. Fullerton, Department of Medicine, University of Aberdeen; Miss M. H. Roscoe, Lister Institute, London; Dr. D. Sheehan, Department of Anatomy, University of Manchester; Dr. S. Zuckerman, Department of Anatomy, University College, London. Dr. Sheehan's fellowship is tenable at Montreal; the others at centres in the United States.

THE annual field meeting of the Association of Economic Biologists will be held on July 14 at the University of Reading. Visits will be made to the University Horticultural Station, the Agricultural Botanic Garden and the National Institute for Research in Dairying. Further information can be obtained from Prof. R. H. Stoughton, The University, Reading.

THE fifty-second annual meeting of the Society of Chemical Industry will be held at Newcastle-on-Tyne on July 10-14, under the presidency of Dr. R. H. Pickard, who has chosen for the title of his presidential address "The Industrial Use of Textiles". Several discussions have been arranged by the various groups of the Society. Further information can be obtained from Mr. J. W. Craggs, 4, St. Nicholas Buildings, Newcastle-on-Tyne, 1.

THE fourth International Congress for Applied Mechanics will be held at Cambridge on July 3–9, 1934. All persons interested in the subject are invited to attend and submit papers. It is suggested that the subjects be grouped as follows: rational mechanics, including vibrations of structures and machines; mechanics of fluids, including turbulence, the boundary layer, heat transfer and compressible fluids; materials, including elasticity, plasticity, fatigue and crystal structure; water waves, including resistance and stability of ships and seaplanes. Further information can be obtained from the Secretary, Fourth International Congress for Applied Mechanics, Engineering Laboratory, Cambridge.

THE prospectus of the German Chemical Plant Exhibition ('Achema VII') to be held in Cologne on May 18–27, 1934, has recently been issued. The annual general meeting of the German Chemical Society and other scientific and technical societies will be held in Cologne at the same time. The preparations which have been made from the point of view of technical organisation in the interests of all those taking part in this Exhibition are fully set forth in the prospectus, a copy of which may be obtained free of charge on application to the 'Dechema', Deutsche Gesellschaft für chemisches Apparatewesen E.V., Achema-Geschäftsstelle, Seelze bei Hannover.

WE have received the first number of a new *Journal of the Chinese Chemical Society*, which is to appear quarterly, the editor being Mr. C. L. Tseng, of the National University of Peking, Peiping, China. This contains several original communications, in English, including studies on Chinese natural products.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An inspector of wireless engineering to the Air Ministry—The Secretary, Air Ministry, Adastral House, Kingsway, London, W.C.1 (June 26). Temporary civil engineering assistants for the Directorate of Works, War Office—The Under-Secretary of State (C.5), War Office, London, S.W.1 (June 28). A city engineer and surveyor of the City of Bradford—The Town Clerk, Town Clerk's Office, Bradford (July 1). A woman assistant chiefly in organic and inorganic work at the Air Ministry, Kidbrooke—The Secretary (I.E.2), Air Ministry, London, W.C.2 (June 30). A technical assistant on the scientific staff of the Fishery Board for Scotland—The Secretary, Fishery Board for Scotland, 101, George Street, Edinburgh, 2 (July 5). A University reader in zoology at Birkbeck College—The Academic Registrar, University of London, S.W.7 (July 10). An assistant curator of the Royal Albert Memorial Museum, Exeter—The Town Clerk (July 12). A teacher of machine drawing, electricity and mathematics at the Chatham Junior Technical School—The District Education Officer, 15, New Road Avenue, Chatham. A head of the Physics Department of the Swansea Municipal Technical College—The Director of Education, Education Offices, Dynevor Place, Swansea.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electron Polarisation?

SOME years ago I published, in collaboration with Mr. H. Jones[1], a paper in the course of which certain experimental observations were recorded on electrons which had passed through hydrogen gas and had suffered therein two inelastic collisions. Certain arguments were based on these observations from which a determination of the probability of effective collision was obtained. In some very recent work in this laboratory, I have been attempting to use the same method in the case of helium, using apparatus of a very much more refined character. Briefly, narrow electron beams are used of velocities between 50 and 400 volts which pass through helium at low pressure making elastic and inelastic collisions on the way. The beam can be oriented at various angles with respect to fine slits through which, at the zero angle, the beam passes. After the beam has passed through the slits, they enter a magnetic field at right angles to their path, are deflected through 180°, and are then recorded photographically on a film. The film on development shows a magnetic spectrum, exhibiting not only the full velocity line (*F* in Fig. 1) corresponding to those electrons which have proceeded straight through the slits from the gun or have suffered only elastic collisions on the way, but also at lower velocities various narrow lines corresponding to energy losses, the most probable of which I have previously shown to be that corresponding to the transition $1^1S_0 - 2^1P_1$. This loss line (L_1) is quite intense and the probability of a collision of the type necessary to produce this loss has been accurately measured in this laboratory at various impact energies.

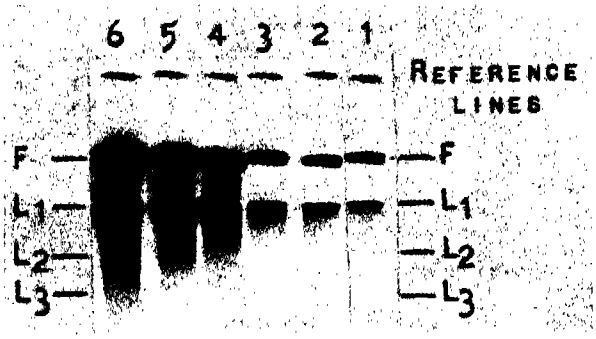

FIG. 1. Magnetic spectra of 300 volt electrons making inelastic impacts in helium. Second inelastic collisions occur only with small probability.

It occurred to me to try to obtain, by lengthening the time of exposure, a mark on the film corresponding to two collisions of this kind. I refer to this line on the film as L_2. It appears to be difficult to get it. At zero angle the probability of its production—that is to say as measured by the ratio of the intensities L_2/L_1 corrected, of course, for the disparity of the paths of the *F* and L_1 electrons—is much less than the corresponding ratio L_1/F. Very careful observations have been taken in order to eliminate all possible experimental 'snags', but there is no doubt that at zero angle and at velocities of several hundred volts the effect occurs. At the same time, it is a striking fact that the L_3 loss corresponding to three collisions is obtainable, and in fact the probability L_3/L_2 is much greater than is to be expected from a simple point of view.

The experiment has been extended from zero angle and it appears that the L_2 loss at three or four hundred volts reaches a maximum intensity at three or four degrees, but at thirty degrees is entirely absent in spite of the very high intensity of L_1.

These are remarkable facts and one explanation which suggests itself, with due diffidence in view of the smallness of relativity spin on the quantum theory, is that the inelastically scattered electrons from helium are polarised. It seems clear that they are in some manner different from the original electrons which leave the electron gun, for had they been precisely similar the probability of a further inelastic collision would have been precisely the same.

I propose to extend these observations to larger angles than thirty degrees and to gases other than helium.

Some results are shown in Fig. 1. There are twelve different exposures on this film, the six lines at the top having been taken with a smaller magnetic field to serve the purpose of reference lines for intensity measurement. The six spectra shown below are of increasing times of exposure from right to left. The absence of L_2 is to be noted (though it is just visible in 5)—and the presence of L_3 in 5 and 6. The photographs lose a good deal in reproduction.

The University,
Leeds.
June 12.

R. WHIDDINGTON.

Structure of the Molecule of 12-Phosphotungstic Acid

THE structures and formulæ of the heteropoly acids have long been a subject for speculation. In 1929, Pauling[1], on theoretical grounds, proposed a structure for the molecules of the 12-heteropoly acids, which gave the formula of 12-phosphotungstic acid as $H_8[PO_4.W_{12}O_{18}(OH)_{36}]nH_2O$.

The structure of 12-phosphotungstic acid has recently been found in this laboratory by X-ray analysis, using the powder method. The phosphorus atom is at the centre of a regular tetrahedral group of four oxygen atoms, and each tungsten atom is approximately at the centre of a distorted octahedral group of six oxygen atoms. The complex acidic anion is a co-ordinated structure consisting of a central PO_4 group surrounded by twelve WO_6 groups as a shell, linked together by shared oxygen atoms. The arrangement differs from that proposed by Pauling. The complex anion is found by experiment to be $PW_{12}O_{40}^{-3}$, and has the point group symmetry *Td*. The twelve WO_6 octahedra are arranged in four groups. Each group consists of three WO_6 octahedra arranged round a trigonal axis, so that the co-ordinates of the three tungsten atoms are of the type (*a*, *a*, *b*) (*a*, *b*, *a*) (*b*, *a*, *a*), with two co-ordinates equal, referred to the rectangular axes of cubic symmetry, with origin at the centre of the central phosphorus atom.

Fig. 1 shows the arrangement of one group of three WO_6 octahedra relative to the PO_4 tetrahedron. Considering at first only this one group of three octahedra, there is one oxygen shared in common between the three WO_6 octahedra and the central

PO_4 tetrahedron, and each octahedron shares two other oxygens, one with each of its two neighbours. Thus each octahedron has two edges shared, one with each of the two neighbouring octahedra. Four such groups of three octahedra are arranged round the central PO_4 tetrahedron in tetrahedral symmetry, so that each oxygen of the PO_4 tetrahedron is now an oxygen already shared between three WO_6 octahedra.

The complete acidic anion $PW_{12}O_{40}^{-3}$ is shown in a simplified form in Fig. 2. It will be seen that each WO_6 octahedron, besides sharing two oxygens with octahedra in its own group of three, also shares two oxygens with octahedra in other groups. In the complete acidic anion each WO_6 octahedron consists of one oxygen shared between three WO_6 octahedra and one PO_4 tetrahedron, four oxygens shared between two WO_6 octahedra, and one oxygen unshared with other polyhedra. The twelve tungsten atoms lie on a sphere with the most even distribution possible, each tungsten atom being equidistant from four other tungsten atoms.

In the partially dehydrated acid examined, which contained six or seven molecules of water of crystallisation per molecule of acid, these acidic anions pack together with body-centred cubic symmetry, of point group symmetry T_d^3. The edge of the unit cube is 12·14 ± 0·005 A. The water of crystallisation packs in the interstices between the anions. The agreement between observed intensities and those calculated for this structure is good, and proves its correctness.

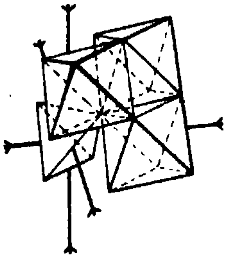

FIG. 1. Arrangement of one group of three WO_6 octahedra relative to the central PO_4 tetrahedron.

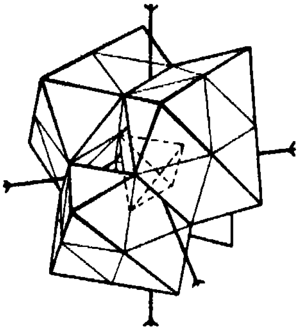

FIG. 2. Complete complex anion, $PW_{12}O_{40}^{-3}$.

This structure gives the formula of the molecule of 12-phosphotungstic acid as $H_3PW_{12}O_{40}$. The formula of the acid is perhaps best written $H_3P(W_3O_{10})_4.nH_2O$, to indicate that the anion is a modified PO_{40}^{-3} tetrahedral group, in which each of the four oxygen atoms has been replaced by a $W_3O_{10}^{-3}$ group, each $W_3O_{10}^{-3}$ group consisting of three WO_6 octahedra sharing oxygens with other octahedra. This formula agrees with the mass of chemical evidence. This work will shortly be published elsewhere in more detail.

It has been proved that the molecule of several other 12-heteropoly acids also have this type of structure, which is apparently the structure for the whole series of the 12-heteropoly acids. This examination of other acids is not yet complete. Work is also in progress on the structures of other hydrates and salts of the heteropoly acids. J. F. KEGGIN.

Bands in the Thermoluminescence Spectrum of Fluorite from Obira, Japan

THE natural thermoluminescence spectrum of almost colourless fluorite from Obira consists of six distinct narrow bands, namely, α_1, α_2, α_3, β_1, β_2 and β_3. Denoting the wave number by ν, it has been confirmed experimentally that $\nu_{\beta_1} - \nu_{\alpha_1}$, $\nu_{\beta_2} - \nu_{\alpha_2}$, $\nu_{\beta_3} - \nu_{\alpha_3}$ are constant, therefore it seems to be plausible to separate the six bands into two groups, α_1, α_2, α_3 and β_1, β_2, β_3. This is indicated in Fig. 1 and the accompanying table. From these results the energy levels assumed in the fluorite phosphor are as shown in Fig. 2.

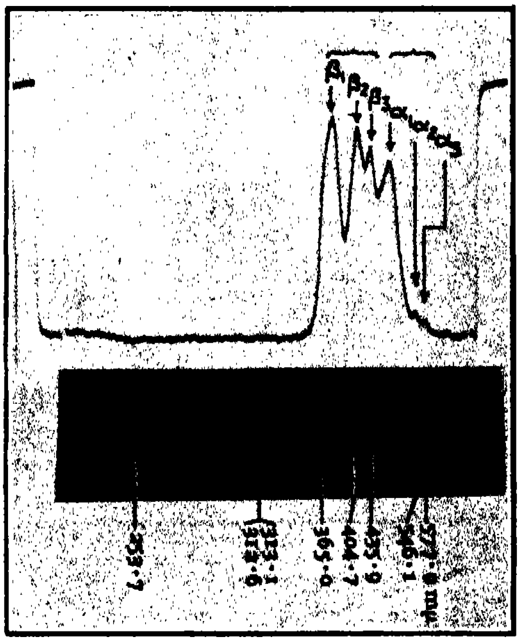

FIG. 1. Above, photometric curve of natural thermoluminescence spectrum. Below, spectrum of natural thermoluminescence and of mercury.

α-group	λ(mμ)	ν (cm.⁻¹)	β-group	λ(mμ)	ν (cm.⁻¹)
α_1	478	20900	β_1	380	26300
α_2	542	18500	β_2	420	23800
α_3	574	17400	β_3	436	22900

$$\Delta\nu_1 = \nu_{\beta_1} - \nu_{\alpha_1} = 5400$$
$$\Delta\nu_2 = \nu_{\beta_2} - \nu_{\alpha_2} = 5300$$
$$\Delta\nu_3 = \nu_{\beta_3} - \nu_{\alpha_3} = 5500$$
$$\Delta\nu \text{ mean} = 5400$$

When the specimen was heated until all natural thermoluminescence disappeared and then irradiated by X-rays (from a Coolidge tube with a molybdenum anticathode, working at 10 milliamperes and 40 kilovolts), it gives, as will be seen in Fig. 3, the thermoluminescence spectrum, the wave-lengths of which coincide with those of the natural thermoluminescence. A comparison of the two photometric curves reproduced in Figs. 1 and 3 shows, however, that there is a remarkable change in the relative intensities of the bands; in the natural thermoluminescence the intensity of the α-group bands is weaker than that of the β-group, while in the restored thermoluminescence the former is definitely stronger than the latter. Further, in each group the longer the wave-length of the band, the weaker the intensity, and this relation remains always unchanged.

The specimen treated with X-rays to restore its thermoluminescent power, emits, when heated, the bands belonging to the α-group at temperatures lower than 200° C. On the other hand, the bands belonging to the β-group are emitted only when the temperatures exceed 200° C. Thus we can separate these two groups thermally.

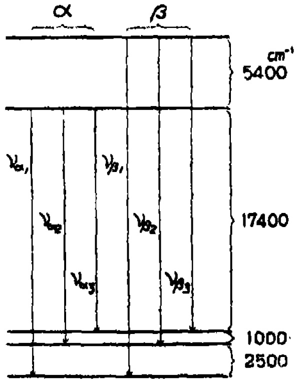

FIG. 2.

It is also of interest to note that the oxides of rare earths extracted from this specimen were proved to be colourless and extremely small (0·004 per cent) in amount.

Similar investigations were carried out on several other specimens of fluorite, but such regular results as the above have not so far been obtained.

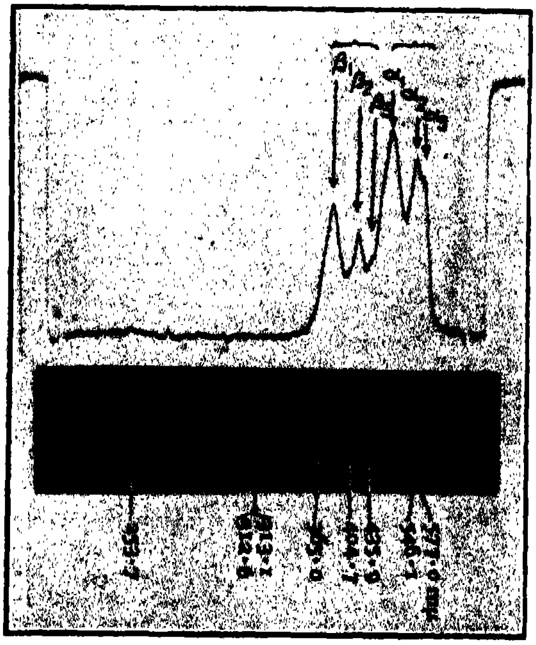

FIG. 3.—Above, photometric curve of thermoluminescence spectrum restored by exposure to X-rays. Below, spectrum of restored thermoluminescence and of mercury.

Form and Vibrational Frequencies of the Nitrogen Dioxide Molecule

MESSRS. HARRIS, BENEDICT AND KING in a recent letter[1] have criticised our deductions and experimental data for nitrogen dioxide. They raise points of general interest which therefore merit reply.

We would first point out that our work on the structure of triatomic molecules has led to certain conclusions which apparently make it possible to predict the normal structure of such molecules. It seems that if the electrons available for molecular binding are insufficient to occupy the necessary molecular properfunctions, as they are in the case of an odd molecule, the structure of the latter is probably that of the next higher molecule, and with the addition of electrons this structure opens out[2]. Thus water (H_2O) and chlorine monoxide (Cl_2O) have a vertical angle in the neighbourhood of 90°, but chlorine dioxide (ClO_2) is like sulphur dioxide (SO_2) with 120° for this angle. If this rule holds, nitrogen dioxide (NO_2) will be like carbon dioxide (CO_2) and the nitrite ion in aqueous solution, which are rectilinear.

It is difficult to know what is the structure proposed by our critics. If by slightly bent, they mean a vertical angle of, say, 170°, we think this an unlikely equilibrium condition, having little mechanical significance. On the other hand, if the value suggested is near 120°, there would be no difficulty in perceiving the second fundamental frequency assumed by them but actually missing from the observed spectrum.

We would emphasise that the proper place to look for the fundamental frequencies of the ground state of any molecule is where they occur, that is, in the infra-red spectrum. It seems to us that to select frequency differences from the ultra-violet, and then to adjust the infra-red spectrum to suit, is the inverse of the correct procedure, and leads to incorrect results as in the well-known case of chlorine dioxide[3]. It is by this method, however, that Harris, Benedict and King assume the fundamental frequencies of 751 cm.$^{-1}$ and 1321 cm.$^{-1}$; as these authors have only examined the infra-red spectrum between 1 and 4 μ, whereas our results extend to 18 μ, they have still less justification for their assumptions and criticisms. By the courtesy of Prof. T. M. Lowry, we have been privileged to see a proof of the results of Sutherland's recent examination of the spectra of NO_2 and N_2O_4: in agreement with our measurements, the first of these frequencies is present in N_2O_4, but disappears completely in NO_2; the second is missing from our spectrum, but is shown by Sutherland to be due to formation of sodium nitrite on the rocksalt windows in the cases where it has been recognised. Since a strong band does exist at 641 cm.$^{-1}$, it is better to take this as a fundamental frequency, particularly since Harris, Benedict and King admit that all their bands can be accounted for by our assignments.

These investigators also apply certain deductions of Gerhard and Dennison to show that the intensity of an expected *Q* branch is small. On further reading, they will see that the work cited deals with the symmetrical rotator, and has no connexion with the present case. If the molecule were like sulphur dioxide or chlorine dioxide, the *Q* branch would be very powerful.

The complex spectra observed in the ultra-violet may be due to other easily excited electronic states, and since the frequency differences observed do not occur in the infra-red, they must be so. Furthermore, if nitrogen dioxide (NO_2) loses its odd electron it will have the sulphur dioxide (SO_2) structure with the obtuse vertical angle.

Finally, we fail completely to understand why the term 'molecule' should not be applied to N_2O_4. To attribute the existence of this substance to a "short-lived partnership" between two NO_2 groups is contrary to the chemical and physical stability of the molecule, which leads and has a life altogether different from such physically stable and spectroscopically well recognised molecules as OH, CH_2, etc. The underlying assumption of the authors leads to the undoubtedly erroneous statement that all the frequencies of NO_2 appear in N_2O_4. With the formation of a new molecule we have new fundamental modes of vibration, and new frequencies.

---

[1] NATURE, 131, 621, April 29, 1933.

[2] Cassie, NATURE, 131, 438, March 25, 1933.

[3] Bailey and Cassie, *Proc. Roy. Soc.*, A, 137, 622.

RECENTLY Bailey and Cassie[1] have reported observations on the infra-red absorption spectrum of the gas mixture of NO_2 and N_2O_4. Harris, Benedict and King[2] have directed attention to the fact that the results of Bailey and Cassie are, in some respects, not in agreement with their observations and the results of previous investigators.

Bailey and Cassie obtained a spectrum for this gas with absorption bands at 15·6, 13·4, 7·92, 6·17, 5·75, 3·22 and 2·91 μ at room temperature, and report the disappearance of all the bands except those at 6·17 and 15·6 μ at a temperature of 100° C.

The infra-red absorption of this gas in the range 2 μ to 16 μ has been investigated by me. Bands were found at 15·6, 13·3, 7·85, 7·28, 6·14, 5·7, 3·89 and 3·3 μ at room temperature. These bands were then examined at temperatures ranging from 3° C. to 150° C. The bands at 3·89, 5·7, 7·85 and 13·3 μ were decreased in intensity as the temperature was increased and disappeared entirely at 150° C. They are therefore attributed to N_2O_4. The bands at 3·3, 6·14, 7·28 and 15·6 μ remained at the higher temperatures and were decreased in intensity as the temperature was lowered, and are therefore ascribed to NO_2. These experiments were carried out with considerable care and the results can be stated with some degree of certainty.

If the bands at 7·28 μ (ν_1 = 1373 cm.$^{-1}$), 15·6 μ (ν_2 = 641 cm.$^{-1}$), 6·14 μ (ν_3 = 1628 cm.$^{-1}$) are taken as the fundamental frequencies of the NO_2 molecule, the 3·3 μ band can be accounted for as the overtone, $\nu_1 + \nu_3$. This selection of frequencies is consistent with an obtuse isosceles triangular structure with an apex angle of about 115°, when the bonds between the N-atom and the respective O-atoms are assumed to be equal. The spectrometer used did not permit resolution of any of the bands into rotational fine structure, and therefore no definite conclusions regarding the structure of the NO_2 molecule can be derived from these observations.

These results are somewhat in agreement with those obtained by Harris, Benedict and King from the absorption spectra of this gas in the visible and ultra-violet, and substantiate their argument that the structure of the NO_2 molecule is not linear. The frequency, ν_1, which they give as 1321·1 cm.$^{-1}$ probably corresponds to the band at 7·28 μ (1373 cm.$^{-1}$) observed by the author in the infra-red. This band, as predicted by Harris, Benedict and King, is less intense than the other two fundamentals, and apparently was not observed by Bailey and Cassie. However, it does not appear probable that the frequency at 751·1 cm.$^{-1}$, which Harris, Benedict and King assign to ν_2, the deformation frequency, is a fundamental of NO_2, since the infra-red band at 13·3 μ corresponding to this frequency is due to N_2O_4 and is not present in the spectrum of NO_2.

From these considerations it appears very likely that the fundamental frequencies of the NO_2 molecule are 641, 1373 and 1628 cm.$^{-1}$.

Details of the above results will be published elsewhere.

Crystal Structure of Vitamin B_1 and of Adenine Hydrochloride

CRYSTALS of vitamin B_1 (hydrochloride) from various sources have been examined. All have been found to be substantially identical in form and X-ray patterns. A very slight difference in optical properties may, however, point to the existence of a variable amount of impurity in solid solution. The angle between the *c* axis and the principal direction γ is 19° 40′ ± 20′, 19° 20′ ± 20′, 19° 20′ ± 20′ and 19° 0′ ± 20′ in four specimens prepared respectively by Windaus and Tschesche, Jansen and Donath, and Peters (two specimens separated at different *p*H). The crystals were monoclinic, tabular on *b* and slightly elongated along *c*, showing faces (010), (110), (011), and sometimes (1 KT) and (2 KT). The cell dimensions are: a = 12·62 A.; b = 20·53 A.; c = 6·96 A.; β = 66° 5′. The space group is probably $C_{2h}^5 - P2_{1/a}$ Assuming four asymmetric molecules per cell and the measured density 1·43, the molecular weight is 358, in good agreement with 355 calculated from the formula of Windaus[1], $C_{12}H_{18}O_2N_4S$, 2HCl. The optical properties are: optic axial plane *b*, γ is 19° 20′ from *c* in acute angle; optic axial angle large, undetermined, sign probably negative, birefringence high.

Combining the indications, it is possible to form some idea of the size and shape of the molecule. The molecules must be flat, of dimensions some 8 A. × 10 A., suggesting conjugated ring structure; they must be nearly in (20$\bar{1}$) planes and form a double layer parallel to (010). The intensities of (020)*m*, (040)*m*, (060)*st* show that the heavy atoms S, Cl do not both lie at the ends of the molecule. Beyond that it is impossible to go at present, but if alternative chemical formulæ could be prepared, there exists enough X-ray data to discriminate between them.

As mentioned in recent letters to NATURE[2], there is a close resemblance between the crystals of vitamin B_4 prepared by Peters, and adenine hydrochloride. This has been fully confirmed by our crystallographic investigations. In external form and optical properties the two crystals are identical. The only difference that could be detected was that the B_4 crystals, of which not more than 0·01 mgm. was available, appeared slightly inhomogeneous, one component possibly differing from the others, and from adenine hydrochloride by at most 0·3 per cent in spacings.

The crystals were monoclinic, tabular on *c* and slightly elongated along *b*, showing faces (001), (100), (011) and (110). The cell dimensions are $a = 8{\cdot}71 \pm 0{\cdot}015$ A.; $b = 4{\cdot}80 \pm 0{\cdot}005$ A.; $c = 20{\cdot}00 \pm 0{\cdot}05$ A.; $\beta = 62° 0'$. There are four molecules of the hydrochloride and two of water per cell. The space group is probably $C_{2h}^4 - P2/c$. It may, however, be $C_s^2 - Pc$, as some crystals seem hemihedral, though there is no trace of pyroelectricity. In either case the molecules are asymmetric. The optical properties are: optic axial plane *b*, γ is 8° from *c* in obtuse angle; optic axial angle medium; sign positive; high birefringence. This is a typical structure for condensed ring molecules arranged in two layers with their principal directions nearly parallel to the *c* axis, and their ring planes inclined 30°–40° out of the (100) planes.

This investigation would seem to suggest that the substance showing B_4 activity can only exist as an impurity in the crystals prepared by Peters. There are three possibilities:

(*a*) The impurity is in the form of an amorphous material adsorbed on the crystals, or if it is in solid solution it must either:

(*b*) be present in extremely minute quantities; or

(*c*) itself be a substance closely allied to adenine hydrochloride.

Mitogenetic Radiation of Nerve

IN his paper entitled "The Physical Nature of the Nerve Impulse" published in the Supplement to NATURE of April 8, Prof. A. V. Hill has criticised a series of papers on mitogenetic radiation which have appeared from my laboratory. Although my name is not mentioned, I wish to reply as I bear complete responsibility for the whole series.

My first remark refers to Prof. Hill's description of our technique. He confines himself to the method of checking the effect—counting the cells—whereas the investigations described in the papers of Kalendaroff and Braines, quoted by Prof. Hill, had been made solely by the mycetokrit method, the experimental and control yeast suspensions being centrifuged in calibrated tubes (mycetokrites), that is, by a method analogous to the so-called hæmatokrit. The detailed description of this method given by both authors was accompanied by photographs illustrating a successful experiment. The same method had been also partially used by Schamarina. This omission by Prof. Hill is, to my mind, of great importance, because if in the case of counting the cells one might suspect the investigator of being subjective, not doubting his *bona fides*, then the subjective moment in the results with mycetokrit would mean open-eyed falsification of the experiment. The results described in the papers quoted had actually been based on a large number of experiments (approximately 1,200 by Kalendaroff, 400 by Braines, 100 by Schamarina).

My second correction would be the following. Only two papers out of four were mentioned by Prof. Hill, whereas two others have been passed over in silence. How is this silence to be understood? If Prof. Hill did not object to them, then at least one of the papers criticised—that of Kalendaroff—was rehabilitated, because both those unmentioned contain nerve radiation spectra nearly identical to those described by Kalendaroff. If, on the contrary, Prof. Hill did not consider them trustworthy, then he certainly should not have missed the opportunity of utilising them to convince the reader that our work was fantastic.

Let us pass now to Prof. Hill's remark about Schamarina's paper. The argument: "When two impulses start at opposite ends of the nerve they meet in the middle and stop, but again the whole of the nerve has gone through the active phase. If radiation is given out as the result of nerve activity, its emission should occur equally in the two cases" seemed to Prof. Hill quite indisputable, whereas neither Schamarina nor any other author ever stated that there existed or had been proved a simple constant relation between the nerve disturbance and radiation; that is, that the excitation and the chemical processes in the nerves should always be followed by radiation which could be detected by our means. On the contrary, in different passages of Kalendaroff's paper, as well as in my introduction, there was pointed out the unexplained fact that different spectra which had to be considered as elementary (such as glycolysis, action of phosphatase, etc.) only appeared partly in the nerve radiation. A most striking example of this kind was the indication made by Kalendaroff of the absence of the glycolytic spectrum between the electrodes, where the disintegration of sugar no doubt occurred, perhaps even in a higher degree. From the above it follows only that our data and in particular those given by Schamarina contain some facts not yet explained. It may be considered as a commonplace, that with each discovery bringing explanations of the hitherto unexplained, new problems, sometimes more complicated ones, arise. Even the alternative: "If the results are true, we need a new picture of the propagated disturbance in the nerve" put forward by Prof. Hill, is not to be feared. There is no reason why this picture should remain unaltered or its substitution by a new one bring disaster on science.

My last remark concerns Braines's paper on the disappearance of blood radiation after fatigue. It is not quite clear whether Prof. Hill doubts the existence of blood radiation itself. Blood radiation as a constant phenomenon has been proved by a number of German and Italian workers. What seemed most strange to Prof. Hill was the fact that "After seven hours' work the girls were completely exhausted", but this conclusion has been created by the author himself. Braines said nothing of "the girls being completely exhausted"; indeed, in his abstract he pointed out that his method for testing fatigue was available for work of moderate difficulty, by which he emphasised that such was his estimation of his chief results (109 experiments).

The case of sixteen hours' work had been treated separately and gave different results.

Prof. Hill's final remark, about radiation from the eyes, might remain undiscussed, but for a possible misunderstanding which might arise from his statement that "The girls apparently had only to look at the yeast cells to set them dividing". Actually, a duration of two minutes with intermittent excitation had been necessary, which means a radiation dose presenting a considerable value on the mitogenetic scale (see my monograph). Radiation emitted by the cornea had been proved heretofore by different investigators of my laboratory in many hundreds of experiments.

Pelvic Filaments of Lepidosiren

IN Mr. G. E. H. Foxon's opinion[1] the experiments which we made in Marajó are insufficient to prove that the function of the pelvic filaments of Lepidosiren is to emit oxygen, although he fully admits that our evidence proves that oxygen was given out by the filaments when the fish bearing them was placed in deoxygenated water. He considers that it is more probable that under natural conditions the filaments are concerned with the respiration of the parent.

Mr. Foxon's first argument is that the eggs are scattered at random in a single layer over the floor of the breeding burrow and that the smooth surface of the egg-shells makes it physically impossible for them to be piled up in a heap round which the parent could be coiled up. Dr. Carter, who saw the nests himself in Paraguay, states that they are made of dead leaves and grass, collected by the parent and taken into the burrow, and that among these plant materials the eggs are laid. He also states that the male which guards the nest is found coiled round the mass of leaves and eggs in an expansion at the end of the burrow. In Marajó, nests were brought to us each consisting of a mass of weed and plant debris within which the eggs were contained. The fishermen who brought our specimens informed us that the nests were taken from the end of the burrow, and we found that the eggs in them were alive and developing. Our evidence from the Amazonian region is thus in agreement with that of Dr. Carter from Paraguay.

Mr. Foxon's second argument is that repeated visits to the surface, which would have to be made if the male were in any way a means of supplying oxygen to the young, would be seriously detrimental to the welfare both of the male and of the offspring; to the former because the filaments might be bitten off by an enemy, to the latter because, in the absence of the male, enemies might enter the nest and devour eggs and young. He concludes therefore that the male remains in the nest and respires by means of the filaments. He regards the filaments as a means of diminishing the need of frequent absences of the male from the nest.

Mr. Foxon omits to discuss or even to mention the question whether there is enough oxygen in the water in the burrow to provide for the respiration of the male through the filaments, or even any oxygen at all, and the other essential question, that of the respiration of the larvæ. Carter and Beadle found from their experimental researches in Paraguay that there was scarcely ever a measurable amount of oxygen in the water at the bottom of the swamp at the season and in the region in which the nests of Lepidosiren were made, that the water in the nest-burrows would therefore contain scarcely any oxygen or none at all, unless a supply was obtained from the parent fish. In Marajó we made no special investigation of the oxygen content of the water at the bottom of the swamp where Lepidosiren nests were found. The few tests we made of water from the bottom of shallow swamp-pools gave from 0·39 to 0·95 c.c. oxygen per litre. On the other hand, we often used water which had been deoxygenated by enclosing a small fish in it to the exclusion of air, and the average amount of oxygen left at the death of the fish was 1·5 c.c. per litre. It is certain from all the evidence we have, that the water in the nest-burrow of Lepidosiren is much below this, if not actually zero.

Carter found that the larvæ kept their external gills for 45 days after hatching and therefore probably remained in the nest for that period. Additional oxygen could not be obtained from the water outside the burrow, and the only possible conclusion is that if the male did not visit the surface at frequent intervals to fill its lungs with air, both it and the larvæ would die of asphyxia in a much shorter period than 45 days, or even 45 hours.

The conditions in the experiments carried out by us in Marajó were essentially similar to the natural conditions to which the male Lepidosiren and the larvæ are subjected in the nest-burrow. The male in the burrow is free to visit the surface at the necessary intervals, while the male in our experiments could inspire at will. The male in our experiments gave off oxygen from its vascular filaments to deoxygenated water in a glass tube, the male in the nest-burrow with air in its lungs must necessarily give off oxygen to the water in the burrow, which contains less oxygen per litre than the water in our tubes.

---

[1] NATURE, 131, 732, May 20, 1933.

IN the last paragraph of their letter, Messrs. Cunningham and Reid state, "The male in the burrow is free to visit the surface at the necessary intervals . . ." This is what I deny. The male is not free to visit the surface but must remain on guard over the young. All who have collected Lepidosiren material agree that the male *guards* the offspring. Prof. Agar[1] has written: "The eggs are placed at the end of the burrow, and the male lies in the passage leading to it, ready to defend his home with his powerful teeth—as I proved unintentionally on my own person, by putting my hand into a burrow from which I thought that the male had been driven out. I quickly drew it out again with my little finger cut open." In the next sentence, Prof. Agar continues: "The devotion of the male lungfish is truly admirable, for he stays in the nest the whole time, from the moment the eggs are laid till the young are ready to leave the nest, a period of about seven weeks."

With regard to the amount of oxygen in the swamp water, it was found both by Prof. Graham Kerr and by Dr. Carter[2] that eggs and larvæ lived satisfactorily and continued their development when kept in pots and in holes in the ground, both of which were filled with swamp water; no means of supplying oxygen to this water was found necessary, so it must be that the amount of oxygen in the swamp water is enough to supply the needs of the young Lepidosirens. In this connexion I am not disposed to regard as final the estimations of the oxygen present in the swamp waters of the Chaco as determined by Dr. Carter and Mr. Beadle, for Mr. Beadle[3] has since shown that these figures are subject to a correction which may be so great as 1 c.c. of oxygen per litre.

Magnetic Quenching of Tellurium Fluorescence

THEORETICAL considerations on magnetic quenching of iodine fluorescence have been given by Van Vleck[1]. His theory explains the effect as the breaking down of a selection rule (which forbids the radiationless dissociation), in the vicinity of the state represented on the Franck-Condon diagram as the crossing of a stable and an unstable curve.

A similar effect was investigated in this work for visible resonance series of tellurium (Te_2). The potential curves of Te_2 are not known very exactly but the works of Heil[2] and Hirschlaff[3] permitted the inference that there exist possibly conditions necessary for magnetic quenching. Moreover, the comparatively large atomic weight suggested that the spin-orbit interaction might appear sufficiently strongly to be the deciding factor between stable and unstable states. The resemblance of tellurium to other elements of the sixth column of the periodic classification suggested the possibility of ascribing the visible resonance series to $^3\Sigma - {}^3\Sigma$ transitions.

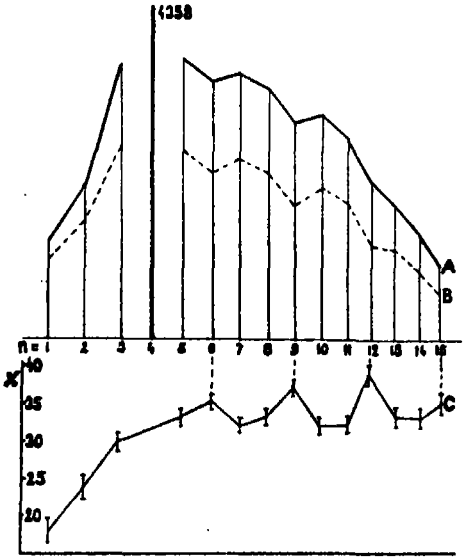

FIG. 1. Curves B and A represent the distribution of intensity in the series of λ4358 in a field of 26,000 gauss and in its absence respectively. Curve C indicates the percentage of quenching and the short vertical lines the probable error of its determination. For n see formula (1).

The electromagnet used in that work gave, in the volume occupied by the tube, a field up to 28,000 gauss. Special arrangements—a detailed description will appear later—made it possible to obtain various pressures and temperatures, the vapour being mostly superheated. The fluorescence was excited with the mercury lines λλ 4358 and 4046, and its intensity found with a Moll microphotometer.

The clearest results were obtained with vapour at saturation pressure for a temperature of 480°–520° C., and superheated to 620° C. The times of exposure were not longer than two hours, which assured a good stability of temperature. The differences of intensity for two exposures in identical conditions were found experimentally to be smaller than 1–2 per cent. The resonance series[4] of λ 4358:

$$\nu = 23{,}930 - 250{\cdot}4n + 0{\cdot}53n^2 \quad . \; . \; . \quad (1)$$

was measured for 11 Stokes and 3 anti-Stokes lines. The quenching in a field of 26,000 gauss amounted to about 35 per cent, and as is seen from Fig. 1, was smaller for anti-Stokes lines than for Stokes lines. The second, fifth, eighth and eleventh Stokes lines (n = 6, 9, 12, 15) which in an unperturbed series have weaker intensity than the mean intensity of their neighbouring lines, were more quenched (35–39 per cent) than the others (32–33 per cent). Neither result is in accord with the supposition that only the excited state is influenced by the field. The quenching of the resonance series of λ 4046 was measured only for the second and fourth lines and amounted to 15 per cent. Other lines were too weak to be investigated or were reabsorbed.

The magnetic quenching of fluorescence, hitherto known for iodine alone and now established for tellurium, indicates the existence of a more complicated mechanism of the effect than had been supposed.

Number 60 in Time Measurements

WITH reference to the note in NATURE of March 4, p. 299, may I point out that the cycle of 60 years does not appear to date back before the Han dynasty (say 200 B.C.), and that the cycle of 60 before that date only occurs in the actual records as applied to days, probably back to about 2000 B.C. There are traces of a 10-day period in the ritual records and this may predate the 60-day period. T. Fergusson considered the 60-years period to have been borrowed from India and to be the cycle of conjunctions of Jupiter and Saturn in the same geocentric longitude, but beyond the fact that Szuma ch'ien used some queer foreign names for the years of the 60 cycle, there is no real evidence.

Research Items

Vai Script. The results of an investigation of the origin of the script of the Vai people of West Africa is recorded by A. Klingenheim in *Africa*, vol. 6, pt. 2. The existence of the Vai script was first reported by F. E. Forbes, a naval officer, in the middle of the nineteenth century. S. W. Koelle, a German missionary, who published an account of the Vai language in 1854, met a native, Momoru Doalu Bukere, who claimed to have invented the script as the result of a dream. European scholars have attributed Vai signs to an origin in European letters, arbitrarily selected to represent syllabic values. Sir Harry Johnston detected Arab influence. Others follow Koelle in recognising the pictorial character of certain signs. Dr. Momolu Massaquoi, a member of the Vai people, is of the opinion that they used a few rude signs expressing concepts before a syllabary was introduced. Other scripts of such a type are found in West Africa. No documents of this character now exist among the Vai, as they were probably written on perishable material. Bukere's invention would appear to have been the substitution of the phonetic syllabary for the older pictorial system then probably in a state of transition. The syllabary possesses two classes of signs: (1) original signs, which go back to a particular picture; (2) derived signs, that is, derived from the original signs by the use of diacritical marks. Among the original signs are representations of particular people, people performing certain actions, spirits, parts of the body, animals and plants, objects of material culture, and symbols for abstract concepts. A special interest of the script lies in the fact that it expresses nuances of pronunciation, and refinements which the study of African linguistics has shown to be essential, while giving an African people's own view of their phonetics.

Yuman Ethnology. The University of California for some years past has had in progress a programme of research on the Yuman family, a distinctive block of tribes of some importance living around the head of the Gulf of California, which previously had been neglected in anthropology. Mr. E. W. Gifford, in contributing a unit element on the Cocopa, a tribe who lived on the Lower Colorado (*Univ. Calif. Pub. Amer. Arch. and Ethnol.*, **31**, No. 5) to these studies, outlines the principal results which have been obtained by the work of the last ten years. The total Yuman territory falls into four natural tracts, each forming a region of distinctive geographical features, each inhabited by a group of tribes whose culture was roughly uniform. So far as known at present the languages fall into groups, corresponding fairly closely to the cultural and geographical divisions. The first group, called by the Spaniards Cochina, held the desert central part and a considerable part of the southern portion of the Californian peninsula. So far as known, they are extinct and merged in the Mexican population. Knowledge of them depends upon documentary evidence. The second area is mountainous and desert, comprising the northern end of the peninsula and a strip of the southern edge of the American State of California. This is the area of the Digueño. The third region is the flood-plain valley of the Colorado from about Needles to the mouth of the river, in which was a string of specialised tribes dependent *mainly on agriculture*—Mohave, Halchidhoma, Yuman proper, Kohuana, Halyikwamai and Cocopa with the Maricopa. East of the Colorado the fourth group of the Yuma held most of north-west Arizona. These were the Yavapai, Walapai and Havasupai. The culture of the Cocopa, the subject of Mr. Gifford's study, is on the same basic pattern as in the other great Colorado river tribes, Mohave and Yuma, although enmity between them was chronic.

Antimony Poisoning from Enamelled Vessels. The Ministry of Health has issued a leaflet (Mem. 171/Med.) on the occurrence of three extensive outbreaks of antimony poisoning due to the use of enamelled vessels, fortunately without fatal results. Acid drinks were prepared in the vessels, in one case from 'lemonade crystals' which contained tartaric acid, in the two other instances from fresh lemons. Antimony oxide is widely used, in the place of tin oxide, as an opacifying agent in the enamelling of hardware of inferior quality on account of its comparative cheapness. The vessels in which the lemonade had been prepared in these outbreaks were examined and it was found that the enamel coating had been attacked and disintegrated by the acid, and the lemonade contained a quantity of antimony in solution.

Crystalline Style in Gastropods. In a paper (Reports, Great Barrier Reef Exped., vol. 1, No. 10, 1932) in which C. M. Yonge describes the feeding and digestion in the gastropod molluscs *Pterocera* and *Vermetus*, a list is given of the genera of gastropods in which crystalline styles are known to occur. In this list are stated the habitat, the feeding mechanisms, the nature of the food and the character of the style sac—whether it is in free or in restricted communication with the intestine or is separate from the latter. Of the forty-one genera in the list, seventeen are marine, four are found in brackish water, seventeen in fresh water, two are amphibious and one (*Pomatias*) is terrestrial, largely subterranean. The general conclusion is reached that in the Gastropoda the style is restricted to herbivorous feeders but is not present in all of these. It is confined to those which feed by ciliary mechanisms or by the slow but almost continuous action of a radula. The style assists in the passage of a continuous stream of finely divided food through the gut, and in the effective mixing of food and enzymes in the stomach; by its slow dissolution in the stomach it is admirably fitted for the liberation continuously of very small quantities of enzyme. The different relations between the style sac and the intestine are regarded as correlated with the habits of the respective animals and not as having a taxonomic significance.

Plant Virus Research. An up-to-date account by Dr. Kenneth N. Smith of the present status of plant virus research, together with an extensive bibliography, is given in *Biological Reviews* (vol. 8, p. 136). A perusal of the review gives the general reader an insight into the difficulties which confront the workers in this field. In the first place, the physical properties of the different viruses are by no means uniform. The thermal death points vary from 80° to 90° C. for tobacco mosaic to 42° C. for spotted wilt of tomato, and whereas the former can withstand diluting to 1 in 10^4, the potato mosaic group are inactivated by quite a small dilution. Further, some viruses retain their infective power *in vitro* for a year or more, while others become innocuous after a storage period of hours only. Of special interest is the section dealing with recovery, carrying power, resistance and immunity. Some authentic cases of recovery are recorded, but the plants were susceptible to reinfection with the same virus. Resistance to a specific virus has been found among individuals of a species or among certain varieties of a plant normally susceptible to that virus, but no development of immunity has been demonstrated. As regards immunological reactions of tobacco mosaic virus, separate antisera are produced in rabbits to normal sap from healthy tobacco plants and to virus sap from mosaic plants. Appropriate quantities of the antiserum to the virus sap completely inactivate the virus sap in this case. Emphasis is laid on the importance of classifying the virus rather than the disease it causes, as hitherto too much stress has been laid on symptomatology alone.

Geology of Rangoon. In his report on "The Geology and Underground Water of Rangoon" (Government Printing Office, Rangoon, 1932, pp. 78, with geological and other maps and sections), Mr. P. Leicester presents the results of a detailed geological investigation of the origin, distribution and behaviour of the underground water which supplies the needs of Rangoon; and makes a series of recommendations for its conservation and future exploitation. Special attention is directed towards the prevention of influx of saline water from the river and the associated deltaic deposits. The work involved the making of a geological map of the area, and this in turn has yielded evidence of oscillations in the levels of land and sea during the Quaternary, comparable with those experienced in Europe during the glacial periods. The rising of the geo-anticline of the ridge that terminates at the Shwe Dagon Pagoda was followed by a fall in sea-level of 250–300 ft., corresponding to the lowering of sea-level of 40 fathoms over the Sunda Shelf described by Molengraaff. Fluctuating recoveries are noted, due perhaps to alternating retreat and advance of the ice-caps. More recently there have been uplifts of the land, witnessed by the formation of denudation terraces, while the latest changes of all are referred to a slight rise in sea-level followed by slight uplifts related to the still growing geo-anticline. These recent movements, marked by earthquakes, appear to take place along fault planes on the western limb of the anticline of the Dagon ridge.

Ice in the Weddell Sea. Tabular icebergs of twenty miles or more in length have been noted from time to time by various antarctic expeditions, but in recent years their number seems to have increased in the Weddell Sea and the South Atlantic, especially the Scotia Sea. In an article in the *Geographical Journal* for May, Mr. J. M. Wordie and Dr. Stanley Kemp discuss recent records of these bergs and their significance. Treating reports by trading vessels of large bergs with commendable caution and confining their arguments chiefly to reports from whalers and expedition ships, the authors conclude that the unusual number of these bergs indicates some exceptional occurrence in the Weddell Sea. On the eastern side, Coats Land, excepting the Stancomb Wills promontory, would not be likely to yield many huge bergs since it seems to rise into high land not far from the sea. The Stancomb Wills promontory could not account for all these bergs even if it had completely broken up, as is possible. The Filchner or Weddell barrier at the south of the sea is certainly in an unstable state but is relatively low and these huge bergs are very lofty. There remains only the unknown south-western side of the Weddell Sea, which on account of heavy pack-ice has never been approached. Messrs. Wordie and Kemp suggest that these bergs come from that coast and indicate extensive changes in that region and the loss of thousands of square miles of barrier ice. These changes may have considerably improved the chances of penetrating that unknown quarter.

Eddy Diffusion. The mathematical treatment of eddy diffusion in the atmosphere demands a knowledge of analytical methods not possessed by the majority of meteorologists, including professional meteorologists. This is unfortunate in view of the great importance of eddy diffusion in many meteorological problems, for example, those involving the transference of heat, moisture, and dust particles, to mention a few. A number of papers dealing with these problems have been written by Taylor, Chapman, and others in Great Britain. The latest work on the subject, by O. F. T. Roberts, of the University of Aberdeen (*Mem. Roy. Met. Soc.*, 4, No. 37), deserves the attention of those interested in the subject. In it the author starts with the hypothesis that the density distribution due to scattering satisfies a functional equation expressing uniformity of scattering power, and shows that from this it can be deduced that the square of the standard deviation of matter scattered from a plane source varies as the time. The method followed in reaching this conclusion is extended so as to show the manner in which this density distribution may differ from that due to the assumption of an eddy scatter analogous to that which arises from thermal diffusion in a solid body. A similar result for homogeneous scattering in three dimensions is derived by further analysis, and finally the scatter from a fixed point or line into a medium with uniform mean flow.

Penetrating Rays from Thunderclouds. Schonland and Viljoen (*Proc. Roy. Soc.*, May) have looked for a connexion between South African thunderstorms and the discharges of a Geiger-Müller counter shielded with iron. The counter discharges and the abrupt electric field changes due to lightning discharges were recorded side by side on a chronograph tape, and special care was taken to ensure that no spurious coincidences were produced by the mutual influence of the recording amplifiers. A statistical analysis of the records showed that for some storms there was a pronounced probability of a counter impulse coinciding with a lightning discharge. A further examination reveals that the probability of counter impulses is slightly increased in the few seconds which precede a flash. None of these effects was observed with storms distant less than 30 km. from the station—with nearer storms there was apparently a reduced probability of counts during the time when the strongly charged cloud was overhead, in agreement with earlier work of Schonland. The upward projection of 'runaway electrons' in the intense electric fields of thunderclouds has been suggested by Wilson. These electrons may be deflected in the earth's magnetic field and produce the results now discovered.

Fluorescence of Zinc Oxide. An investigation by Beutel and Kutzelnigg (*Sitzungsber. Wien. Akad. Wiss.*, 141, 437; 1932) shows that the fluorescence of zinc oxide preparations is a specific property and is not due to traces of foreign metals as impurities. The effect is diminished by powdering the preparation, and the colour of the light is affected by the temperature to which the oxide has been heated. An intensive green fluorescence is obtained with preparations ignited in a reducing atmosphere, whilst the oxide obtained by decomposing the carbonate at 300° shows a dark brown fluorescence. A minimum of fluorescence strength was found with preparations heated at 600°, and the effect disappears when oxide obtained by heating the nitrate is strongly ignited. No definite relation between physical properties and fluorescence could be established.

Copper Age in Ancient China. Further analysis (cf. NATURE, 131, 243; 1933) of three ancient halberds similar to those found on the Yin site at Honan, made by Tsurumatsu Dono (*Bull. Chem. Soc. Japan*, April), showed that one was almost spectroscopically free from tin, another contained only 0·60 per cent of tin, whilst the third contained 2·19 per cent. In the first, 15 per cent of lead was present, in the second 0·58 per cent and in the third 5·85 per cent. Arsenic was either absent or present only as a trace. Since the three objects were almost identical in appearance, it is concluded that the introduction of bronze poor in tin occurred in a transitional period which came between the copper and bronze ages and that this period was very short. The paper contains complete chemical analyses and microphotographs of structure. The close similarity in composition between ancient Chinese and Sumerian bronzes is noteworthy.

Astronomical Topics

Radial Velocities of Variable Stars. Dr. P. W. Merrill contributes an article on this subject to *Popular Astronomy* for April. He refers to the former idea that these were dwarf stars approaching extinction; a study of their proper motions showed that the variables are in most cases remote, so that they are now reckoned as giants, not as dwarfs. The radial velocities are important for giving an estimate of their true speeds, since the thwart velocities are generally too small to determine accurately. It has been observed in many cases that the bright lines visible at maximum show a velocity of approach of about 15 km./sec. relatively to the dark lines. It is concluded in the article that the latter give the true speed of the star, and that the difference arises from an outward motion of heated gases. A strong argument for this is afforded by the close double star *X* Ophiuchi; one component is variable, the other of constant light; at maximum the spectrum of the former is observable, at minimum that of the latter; the dark lines in both stars give the same radial velocity, −70¾ km./sec., while the bright lines in the variable give −83½. A similar argument is drawn from *R* Aquarii and its companion nebula. In some faint variables the bright lines only are measurable. A correction is applied to these to deduce the true velocity of the star. A statistical study then shows that the variables, as a whole, have a mean speed of 37 km./sec. relatively to the other stars, this speed being towards a point in the southern hemisphere nearly opposite the solar apex.

Microphotometry of the Solar Spectrum from 4040 to 4390 A. In the first part of a recent paper (*Annals Solar Physics Observ., Camb.*, 3, Part 2), Dr. R. v. d. R. Woolley develops the mathematical theory, following Eddington's earlier investigations, of the occurrence and the relative intensities of the dark lines in the solar spectrum, on the hypothesis of selective scattering in the sun's atmosphere. The modification of the scattering coefficient due to the Doppler effect is also considered. The observations described in the second part are based on plates recently taken by Evershed at Ewhurst. A plate was cut in two; one half was exposed by Evershed, the other half was standardised photometrically at Cambridge, the two halves being afterwards developed together. The spectrograms were then examined with the Cambridge microphotometer. The tables give the multiplet identification, the central intensity and equivalent breadth of the lines in the part of the spectrum examined. In the third part, Dr. Woolley gives a full discussion of multiplet intensities, the calibration of Rowland's scale of intensities and the classification of solar lines according to contour.

Publications of the U.S. Naval Observatory (Washington). Vol. 13, of 365 pages, of these Publications, contains the observed positions of sun, moon, planets and stars, obtained from observations with the 9-in. transit-circle. The observations of the sun extend from 1918 until 1925, those of the moon from 1913 until 1925. The results are compared with the predictions of the American Ephemeris; in the case of the moon there is a further comparison with an improved ephemeris, in which some corrections to Brown's tables have been applied. In the case of Mars, Ross's corrections to Newcomb were introduced into the ephemeris in 1922, but their effects have been carried back to 1913.

The next item in the volume is a catalogue of 9,989 standard and intermediary stars, between the north pole and declination −36°; they were observed in the years 1913–1926; the positions are reduced without proper motion to 1920. Proper motions have been determined for all the stars. They are given to three or four decimals of a second of time, and to two or three of a second of arc. There follows a catalogue of 2,438 standard stars, and a comparison of the observed positions with those of Greenwich, Boss and Eichelberger.

Full details are given of the methods of observation. The transits were recorded by hand-tapping the passage over fixed wires. Meridian marks were used as a check of the azimuth of the instrument. A diagram shows an interesting correlation between the changes of azimuth of the marks and the motion of the pole determined from the observations for latitude variation. A printing chronograph was used for recording the transits, the times for each wire being read to 0·02 sec.

Nature of Dental Caries

IN a recent paper on the cause and nature of dental caries, J. J. Enright, H. E. Friesell and M. O. Trescher describe experiments designed to elucidate the part played by local factors in the etiology of this disease (*J. Dental Res.*, 12, 759; 1932). The authors first discuss the two chief theories of causation and point out that Miller's bacterio-chemical theory does not explain all the facts. For example, carious areas produced artificially by acid have not simulated natural caries in certain particulars; the carious process may halt for indefinite periods and, finally, dirty mouths are frequently free from caries. After a review of the relation of diet to dental caries, the authors conclude that improper diet is at least an important predisposing factor in the causation of tooth decay, since diets rich in vitamins A, C and D and yielding an alkaline ash, when utilised systematically during the period of development, produce teeth less liable to decay. After eruption, the structure of the enamel cannot be changed by factors acting from the pulp, because there is no circulation in this structure. Moreover, the ameloblasts, the enamel-forming cells, are lost at the time of eruption.

Clinical observation shows that caries begins at the surface of the tooth and only at certain parts of the surface, namely, in pits and fissures, and on the buccal, labial and proximal surfaces near the gum. It does not commence in areas which are scoured by the food during mastication.

In their first experiments, the authors investigated the action of lactic and citric acids at different *p*H values upon the enamel of isolated teeth *in vitro*. They found that artificial caries might simulate natural caries exactly, that all solutions between *p*H 4 and 8 etched enamel and that different enamels varied in their susceptibility to the action of the acids. Further experiments were carried out with the same solutions to which tricalcium phosphate had been added to saturation, since saliva is supersaturated with regard to this salt. It was then found that etching of enamel only occurred in solutions more acid than *p*H 5. It was also noticed that incipient carious areas were insoluble in acid, apparently because they contained an increased amount of organic material: it is suggested that this explains why the natural process often comes to a stop, even when acid-producing bacteria are contiguous to the lesion.

In the authors' second series of experiments, cultures were taken from carious areas and from similar regions in the mouths of persons immune to caries and grown on blood agar and acid galactose-whey broth. Another examination of the same mouths was made 3–9 months after the first: a close correlation was found between the presence of lactobacilli on the first occasion and the advance or development of caries in the interval. The strains of lactobacilli obtained could be divided into two chief groups: Group 1 usually produces a smooth colony and acid without gas in glucose, galactose, levulose, maltose, lactose, sucrose, mannitol, sorbitol, dextrin and salicin, but no acid or gas in raffinose, arabinose, xylose or inulin. Organisms of this group grow at 15° C. and are agglutinated by a Group 1 rabbit antiserum. Group 2 usually produces a rough, fuzzy type of colony, and acid in glucose, galactose, levulose, maltose, lactose, sucrose and raffinose. This type may or may not produce acid in dextrin; it usually does not produce acid or gas in arabinose, xylose, mannitol, sorbitol, salicin or inulin. Strains of this type do not grow at 15° C. and are not agglutinated by Group 1 antiserum. Lactobacilli of intestinal origin can also be divided into two similar groups. The strains of Group 1 were the most commonly found in the mouth.

The evidence adduced in this paper confirms the view that caries is directly due to the growth of lactobacilli in the mouth, the acid produced decalcifying the enamel. Growth of the organisms and close contact of the acid with the teeth are favoured by the presence of food débris in their pits and fissures and between them. The authors state that tests on the results of reducing the number of organisms in the mouth are now in progress and will be reported later.

Fishery Research in Newfoundland

FOLLOWING upon a preliminary survey of the Newfoundland fishing situation and a report on it to the Empire Marketing Board and to the Newfoundland Government, a scheme providing for a five-year period of fishery research in Newfoundland was drawn up. Half the cost of installation and subsequent maintenance of the Laboratory is, by agreement, borne by each of these two bodies. The objects of the scheme are the investigation of the life-histories of the principal commercial fishes with the view of gaining a clearer understanding of their movements and natural fluctuations, and the improvement of some or all of the existing methods of processing and marketing of the fish and fish products. By-products and their possible utilisation also come within the scope of the investigations.

The Laboratory is situated in the outport of Bay Bulls, some 18 miles south of St. John's. It is housed in part of certain spacious fishery premises which, fortunately, were available for this purpose. The buildings are fronted by wharves standing in water up to 20 ft. deep, so that steam trawlers can berth hard by the laboratory premises. Thus situated, right by the water's edge in an active fishing centre, and in the closest juxtaposition with a commercial concern, the Bay Bulls Laboratory appears to enjoy unique facilities for prosecuting fishery research—opportunities which it shows every indication of utilising to the full.

The scheme came into operation on April 1, 1931, and a report[*] upon the Laboratory's first full year's work has now been published, the main object of which is to indicate the general trend and progress of the various researches already under way.

In accordance with the scheme, the work of the Laboratory follows two main lines which may for convenience be termed (*a*) biological and (*b*) applied.

[*] Reports of the Newfoundland Fishery Research Commission. Vol. 1, No. 4: Annual Report for 1931. (St. John's, Newfoundland: Newfoundland Fishery Research Commission, 1932.) 1 dollar,

In the biological investigations the aim has been, during the first year, to make a rapid survey of the marine fauna and its inter-relationships in the waters supporting or directly connected with the fishing activities of Newfoundland. Much work has already been accomplished, and great strides are being made in piecing together the life-histories of the caplin, salmon, Newfoundland herring, haddock, cod, lobster, shrimps and prawns. Particular attention has been given to the short-finned squid (*Illex illecebrosa*), a highly important animal commercially in that it is the staple bait for the fall cod fishery. If it does not arrive in very large numbers, this fishery is a failure and up to one-third of the year's catch is lost. In 1930 and 1931, for example, Newfoundland was bereft of much of its fall fishery owing to shortage of this squid for bait.

In addition to the above, extensive hydrographical observations have also been carried out, the results of which already show that the Newfoundland area is one where contrasting, as well as rapidly changing, physical conditions of sea-water have a profound influence on the fauna.

On the processing or applied side, investigations are being carried out on the properties of Newfoundland cod liver oil from the point of view of marketing possibilities. The processing of dried codfish, bacterial infection of fish products, and preparation of fish meals, fish glue, and soaps from many sources are also receiving attention.

The report closes with some conclusions and recommendations which might well be adopted by the various firms and departments concerned in the improvement of the Newfoundland fisheries ; and in an appendix there is published a very useful "First List of Fishes in the Newfoundland Fishing Area".

Judging from the contents of this report and some technical papers already issued, there can be little doubt that the Director and staff of the Bay Bulls Laboratory are attacking with great vigour and remarkable success the numerous problems with which they are confronted.

South-Eastern Union of Scientific Societies

THE thirty-eighth annual congress of the South-Eastern Union of Scientific Societies was held at Norwich on June 7–10 under the presidency of Prof. E. J. Salisbury, Quain professor of botany at University College, London. The occasion was the first time that the Union has met for its congress in the extreme north of its area, and the attendance was well up to the average.

Prof. Salisbury's presidential address on "The Influence of Man on Vegetation" showed that there are two sides to man's interference with the native flora, elimination and introduction. The relative biological isolation of the British Isles ceased when human intercourse between Great Britain and the Continent began. The idea is prevalent that the chalk downs of the south-east were grassland from time immemorial, but the grounds for this assumption appear quite inadequate. Chalk hills are not unsuited for tree-growth. Neolithic man cultivated even the crests of the hills, and the chalk may have been the nursery of English agriculture. Stress was laid on man as an unconscious agent in dispersal. The rôle of man in this respect has been neglected. Dispersal by birds seems a legitimate subject for examination, but the seeds of plants carried by man in the mud of his feet and his clothes have not received sufficient attention.

After the depauperisation of the British flora during the Glacial period, neolithic man must have brought seeds of weeds with his flax and corn in the absence of all modern screening methods. Calculations show that of the 288,857 cwt. of clover and grass seed imported in 1912, 2–6 billion weed-seeds from abroad were sown in Great Britain. The unconscious carrying of seeds by man was strikingly illustrated by an experiment on the dust collected in sweeping out the pews of two selected churches. Samples of the dust were sown, each sample being about four ounces in weight. The germinating plants in any one sample varied from one to fourteen, about 90 per cent being grasses. Possibly clothed in skins, neolithic man may have carried seeds for considerable distances, even as now Prof. Salisbury finds that man is carrying about viable seeds in his turned-up trousers after a walk on Chesil Beach or on a Hertfordshire common. In the latter case, a walk produced 110 grasses and three dicotyledons.

In a paper by Mr. Hugh Ramage on "Applications of the Spectroscope to Biology" some of the results of research by this means were given. Strontium was detected in the genital duct of the edible snail and manganese was a prominent element in its liver. It was found that, on examining 146 specimens, copper and iron were always present. The highest concentration of silver was found in the liver and kidney of *Pinna pectinata*. Silver was present in every liver of crabs and lobsters examined. Cæsium was always found in the liver of the common scallop. Examination of sea-water always revealed 0·004–0·005 per cent of strontium, which appears to place strontium as the ninth element in order of abundance. Copper was found in all human tissues and occurs in greatest concentration in fœtal tissues and fœtal livers. Rubidium occurs in the heart and striated muscles. Silver appears to be a normal constituent of the thyroid and the tonsil. The edible mushroom yielded copper and silver. Some fungi contain rubidium. The highest percentage of rubidium (dry weight) was found in *Cantharellus cibarius*, namely, 0·21 ; and of silver, 0·20 in the skin of a specimen of *Psaliota campestris*.

Investigations as regards insect immigration have been carried out since the inauguration of the special committee of the South-Eastern Union in 1932, and there are now thirty light-vessels and light-houses with their observers engaged in the work, with some hundreds of inland observers. Useful records have reached Capt. T. Dannreuther and Dr. C. B. Williams, who are responsible for the collating of such records. The Large White butterfly has been observed by L. G. Sharman, of the East Dudgeon light-vessel, for some years. He has seen a stream of these butterflies every year about the middle of June. In 1931 about thirty an hour were seen passing over the ship from east to west. Near Alston, G. Bolam observed a passing band of Small Garden Whites on June 25, 1932. They were steadily pursuing a northerly course at the rate of about a dozen a minute. These are cited as showing the records that it is hoped observers will send in from all parts of the country, with the view of the further elucidation of the immigration problem.

Among the more general papers read at the Congress were "Rural Surveys; Change and Decay and Rebirth" by W. P. D. Stebbing; "Pond-Life, with Special Reference to the Rotifera and Polyzoa", by H. E. Hurrell; "Evolutionary Sequence Amongst Desmids", by Prof. F. E. Fritsch; "The Viking Period", by P. D. Kendrick; "The Relationship of Geology to the Scenery of the Weald", by F. H. Edmunds; and "The Pliocene and Pleistocene Deposits of Norfolk", by J. E. Sainty.

A very full programme of excursions to places of scientific interest was carried out during the Congress. It was announced that the Congress for 1934 will be held at Reading, under the presidency of Prof. H. L. Hawkins, professor of geology in the University of Reading.

University and Educational Intelligence

CAMBRIDGE.—Dr. G. D. H. Bell, of Selwyn College, has been appointed University demonstrator in agricultural biology.

A university demonstratorship in chemistry is vacant. Information concerning it may be obtained from Mr. H. Thirkill, Clare College, to whom applications should be submitted before June 30.

D. Thoday of Trinity College and Dr. F. H. Constable of St. John's College have been approved for the degree of Sc.D.

Dr. K. A. C. Elliott, Beit fellow, has been elected to a fellowship at Selwyn College.

LONDON.—The following degrees have recently been awarded: D.Sc. degree in botany to Mr. C. L. Huskins (King's College) for eight published works on genetics and cyto-genetics; D.Sc. degree in plant physiology to Mr. E. Ashby (Imperial College—Royal College of Science) for nine works, including four papers on "The Interaction of Factors in the Growth of *Lemna*", and two papers on "Studies in the Inheritance of Physiological Characters"; D.Sc. degree in vital statistics to Hilda M. Woods (recognised teacher at the London School of Hygiene and Tropical Medicine) for nine works on medical statistics and epidemiology; D.Sc. degree in zoology to Cherukad Cherian John (Imperial College—Royal College of Science) for a thesis entitled "On the Anatomy, Habits and Development of *Spadella Cephaloptera*" (*Quart. J. Micro. Sci.*, Feb. 1933); D.Sc. degree in chemistry to Mr. A. G. Francis (private study) for four independent publications, entitled (1) "Report on the Investigations carried out by the Experimental Staff of the Departmental Committee on Ethyl Petrol"; (2) "Presence of Barium and Strontium in Natural Brines"; (3) "The Recovery of Radium from Luminous Paint"; (4) "3 : 4-di-*p*-nitrotetraphenylfuran"; together with four conjoint subsidiary contributions.

TO meet the growing demand for biological teaching in schools, a diploma course in biology will shortly be instituted at the University of Leeds, chiefly to meet the needs of teachers qualified in the physical sciences. The course will extend over two years and it is proposed to begin it on October 3. Lectures will be given on one evening a week and Saturday mornings. Further information can be obtained from the Registrar of the University.

ON the recommendation of the Scientific Advisory Committee of the Lady Tata Memorial Fund, the following awards of scholarships, open to graduates of any nationality for research work on diseases of the blood, with special reference to leucæmia, for the academic year 1933–34 have been made: Dr. W. Büngeler, University of Frankfort-on-Main; Dr. L. Dolschansky, University of Berlin; Dr. M. C. G. Israëls, University of Manchester; Dr. C. Oberling, Faculty of Medicine, Paris.

AT a recent council meeting of the Association of University Teachers the position of the recently displaced teachers in German universities was discussed. The Association recorded its continued adherence to the fundamental principle of freedom of opinion and teaching in academic life and stated that it is ready to co-operate in affording facilities at British universities for such displaced teachers, provided that special funds are made available for the purpose. The Executive Committee of the Association appointed a sub-committee to keep in touch with other groups having similar aims, of which the convener is Prof. R. J. Tabor, Imperial College of Science and Technology, South Kensington, London, S.W.7.

WE have received from Armstrong College, Newcastle-upon-Tyne, the report for 1931–32 of the College Standing Committee for Research. This report demonstrates that the researches aided by the Committee's grants, which amounted during the year to £586, are bearing excellent fruit. In addition to giving a list of a hundred publications, the report particularises some results of special interest. A notable addition to the resources of the Physics Department was made possible by a grant of £842 from the Rockefeller Foundation towards the cost of a reflecting echelon interferometer, the research committee undertaking to find the remainder (£300) of the price. An investigation dealing with the use of high-frequency fields to raise body temperatures gave such promising preliminary results that the Medical Research Council made a grant for its continuance. Incorporated in the report are accounts of the work of the Northern Coke Research Committee and the Electrical Engineering Committee of the College.

"The Broad Highway of Soviet Education", as shown to a party of twenty men and women interested in education, is described in a pamphlet recently published by the Society for Cultural Relations between the Peoples of the British Commonwealth and the U.S.S.R. The tour, which took place more than a year ago, included a series of visits and receptions in Leningrad, Moscow, Kharkov (where part of the visit was filmed) and Kiev. The compulsory seven-years school in two stages, 8–12 years and 12–15 years, is said to be based upon correlation with working life. The schools are commonly attached to factories and, so far as possible, all practical work is productive: one of the schools visited was found to be self-supporting. Continued education is provided in technical and factory-apprentice schools for the stage 15–18 years. Higher education is conducted chiefly in single-faculty institutes intended to turn out technical experts in factories, and other specialists.

Qualification for admission generally includes two years' experience of factory life and two or three years of a workers' preparatory course embracing a wide variety of subjects. The writer of the report, Mr. C. A. Harrison, education officer of Messrs. Cadbury Bros., suggests that educational contacts may serve to bridge the gulfs which separate the Soviet system from the rest of the world. He was impressed while in Russia by the apparent prevalence of what he describes as a "wholesome" dread of embroilment in war coupled with a determination to be prepared.

Calendar of Nature Topics

Fourth 'Buchan Cold Spell'.

June 29–July 4. It not infrequently happens that June in England brings an interval of dull weather separating the sunshine of May from the heat of July. In Great Britain at least, the soubriquet of 'flaming June' appears to be a misnomer. On the whole the fluctuations of temperature in June are relatively slight, and the general tendency is for a steady warming up throughout the month without any marked set-backs. At Greenwich the 90-year averages from 1841 to 1930 show that this rise is interrupted by a short period of steady temperatures from June 29 until July 1, but this is too slight to be dignified by the name of a 'cold spell' and there is no reason for supposing that it will be repeated in future years.

Nile Flood

The River Nile is very low during April, May and the early part of June, reaching its minimum at Khartoum about May 11. In June heavy monsoonal rains begin to fall on the mountains of Abyssinia, and throughout July, August and September, immense quantities of water are discharged into the Blue Nile. The main Nile commences to rise rapidly towards the end of June, reaches its maximum level about September 4, and remains high until some time in October. The water fills the irrigation channels and covers much of the flood plain, on which silt is deposited, forming a soil of great fertility. This annual flood is the most important event of the Egyptian year, and river gauges have been maintained since early times to measure its progress and height. Before the building of the great dams, the crops of Egypt were so dependent on the annual flood that the gauge readings were used as a basis for assessing taxation.

Migration and Plumage Coloration of Birds

During the summer months there occur on the mud-flats and sandbanks of northern Holland many wading birds belonging to species which normally should have been at their breeding places in the north of Europe or Asia. A first impression would regard them as immature birds, but G. J. van Oordt has shown that many wear adult summer plumage or some modification of it. On June 23 and 27, 1927, he collected seven knots and fifteen turnstones on the island of Vlieland, and since the very last of the migratory individuals pass through in the end of May or in the first days of June, these were real summering birds (*Tijdschr. Ned. Dierkundige Vereen.*, Ser. 3, 1928, p. 25). Examination showed that the testes of most of the individuals collected were inactive, having formed no spermatocytes, and that although the plumages of such birds varied much, they all possessed in various degrees the feathers of adult summer plumage. Three birds were found to have a relatively large number of spermatocytes and in them the plumage was almost or quite identical with the adult summer phase. From these observations, it would appear that the absence of urge to migrate as well as the failure to replace winter by summer plumage was associated with inactivity of the gonads and that summer plumage in male birds cannot develop until spermatogenesis has started and many spermatocytes have been formed.

Spat-Fall and Shore Populations

In June and July occurs the spat-fall of many shore molluscs, when rock surfaces, seaweeds, and the sand itself begin to be deluged with a rain of minute individuals on the point of settling down after their free-swimming larval life. They are often very small—the shells of recently settled mussels measure about 0·3 mm.—but the number is very great, and this and their rapid growth make them important elements in the shore population. Indeed they have proved to be a nuisance to many coastal towns, for intake pipes have become blocked by the growth of mussels which have settled in them from the passing current. The late Sir William Herdman reckoned that on the seashore about 120,000 mussels might go to the square yard, and Richard Elmhirst finds a similar number on the piles of Keppel Pier at Millport, upon which about 60,000 individuals of the beautiful plumose anemone (*Metridium senile*) also find foothold. At Millport the numbers of the acorn barnacle (*Balanus balanoides*), a crustacean, are still greater. Elmhirst states that in late April the cyprid larvæ may occur 300 to the litre close inshore when swarming in to settle down (*Glasgow Naturalist*, 1932). These small larvæ may settle 200 to the square inch, or more than a quarter of a million a square yard. A heavy mortality, due largely to the molluscs *Purpura* and *Littorina* ensues, so that by autumn they are reduced to 15,000 a square yard. But even the dead ones have contributed to the circulation of organic matter in the shore area.

The Ice Bridge: A Correction

The paragraph under this heading in NATURE for April 15, p. 557, requires some modification. The harbours and waterways of the system of American "Great Lakes" are frozen or blocked by ice, and in Lake Superior ice-fields often extend beyond the range of vision from shore, but in most winters much open water remains, especially in the lower part of Lake Michigan. In February 1904 the lakes were almost completely ice-covered, but this is exceptional.

In many parts of the northern hemisphere the winters of the twentieth century have been generally milder than those of the latter half of the nineteenth, and ice conditions may also have become less severe, but precise information is difficult to obtain, as the greater power of steamers and the extended use of ice-breakers would suffice to keep navigation open longer than formerly. The record of 300 ships held up at one time, which is quoted in the "Gulf of St. Lawrence Pilot", was first published in 1888, and therefore must refer to sailing or low-powered craft, but the actual date of the occurrence cannot now be traced. For the reasons stated, such an occurrence is unlikely to recur.

Societies and Academies

Dublin

Royal Irish Academy, April 24. P. J. Nolan : The influence of condensation nuclei and dust particles on atmospheric ionisation. Fair conformity with Wright's conclusion that dust particles play an important part in the equilibrium of atmospheric ionisation is obtained from a re-examination of previous work. A theoretical basis for the equilibrium equation $q = \zeta n \sqrt{Z}$ is proposed. The combination coefficients of small ions with dust particles and with large ions are deduced. R. F. Scharff : The past wanderings in Europe of two African animals. The manner in which the hippopotamus and the bivalve mollusc *Corbicula* seem to have entered Europe from the south-east in late Pliocene times is described. They probably travelled along the great Rift Valley from Central Africa to Palestine when the Red Sea was still a river valley. The area of the Ægean Sea, while still unsubmerged, afforded an easy passage between Asia Minor and Greece and thus on to Italy and Malta. Their remains occur everywhere in Italy, France and Belgium, but the hippopotamus never crossed the Rhine. Eventually, in the early Pleistocene, both species passed into England, when it was part of the Continent. Special comment is made on the significance of the British distribution of both animals.

Edinburgh

Royal Society, May 15. Norman H. W. Maclaren and Thomas H. Bryce : The early stages in the development of Cavia. A sequel to an earlier memoir by Maclaren. The study was recently resumed in the light of specimens examined in the living state and for more advanced stages of results obtained after intra-vitam staining with trypan blue. A number of blastocysts at earlier stages than those hitherto known are described ; the mode of implantation is re-examined ; the fate of the part of the uterus to the anti-mesometrial side of the site of implantation is demonstrated ; and the significance of the observation that after a preliminary destructive phase the endometrium lining the decidual cavity comes to be packed with maternal cells containing trypan blue granules is discussed. P. F. Kendall and H. Briggs : The formation of rock joints and the cleat of coal. By means of frequency charts for a number of the chief coalfields of Great Britain and the United States, it was shown that the main cleating and jointing system has a north-westerly direction. In some coalfields, such as Yorkshire or Durham, the north-westerly orientation is remarkably consistent ; in others, such as Scotland, it is less definite, though the majority of the values obtained have a north-westerly trend. The authors' records also show that that direction was also maintained over great periods in geological time. The forces responsible for jointing have therefore to be looked for among those incident on the earth's crust down to and including the present time. The Mid and East Lothian coalfields have been specially studied to trace the connexion between cleat and joints and the faults known to exist in that field ; and the effect of faulting on jointing was discussed. The joints and cleat were induced by rapidly alternating torsional stress applied to the earth's crust in a direction approximately parallel with the equator. It is concluded that the alternating torsional stress is due to tidal action, and that the long-continued alternation of stress so applied eventually caused failure of a bed through fatigue. Mary G. Calder : Notes on the Kidston collection of fossil plant slides. (2) The anatomy of the axis of *Bothrodendron mundum* Williamson sp. Certain previously undescribed anatomical features of the aerial stem of *Bothrodendron mundum* are discussed and illustrated. The more important of these are variation in the pith cells, occasional occurrence of marked xylic perforations in the stele, hyphal structure in the middle cortex in certain specimens, and the occurrence in some stems of a ring of cortical tracheidal strands, having no apparent connexion with the outer surface of the stem or with the leaf traces. H. W. Turnbull : Matrices and continued fractions. By the method of matrices it is possible to form the reciprocal of a certain continuant determinant which was first studied by Sylvester. This leads to new expressions for the derivative of a function $f(x)$ as a continued fraction. A series, the nth term of which involves the square of the difference between $f(x)$ and its nth convergent, is discussed. J. L. Gray and Pearl Moshinsky : Studies in genetic psychology (1). Correlation between collateral relatives with respect to intelligence. The correlation with respect to intelligence as measured by the Otis group advanced test for pairs of sibs between the ages of nine and twelve and a half is 0·35 ± 0·05. For pairs of first cousins the coefficient is 0·16 ± 0·06. This investigation, carried out with the same test on children selected in the same way as in Herrman and Hogben's study of twins, establishes the existence of a significant difference between the correlation of fraternal twins and ordinary sibs. The possible existence of sex-linked gene differences with respect to intelligence and the effect of order of birth in the family are also discussed.

Paris

Academy of Sciences, May 8 (*C.R.*, **196**, 1345–1444). A. de La Baume Pluvinel and D. Barbier : The observation of the total eclipse of the sun on August 31, 1932. Observations made at Louiseville, in Canada. Photographic, photometric and spectrographic observations of the corona were made, the results of which are detailed. René Maire, Etienne Foëx and Georges Malençon : The etiology of 'bayoud', a disease of the date palm. A fungus, named *Cylindrophora albedinis*, was isolated from the diseased tissues in 1930 by Maire and Kilian, but no fructification. The mycelium had been met with in the natural state, and attempts at infection were always negative. The formation of intravascular conidia has now been observed and it appears clear that this fungus can be regarded as the agent of 'bayoud'. Some varieties of date palm appear to be resistant to the disease. Frank Schlesinger was elected *Correspondant* for the Section of Astronomy in succession to the late Prof. H. H. Turner. Lucien Chamard : The paratangent of an ensemble equidistant from a point ensemble. G. Ehresmann : A theorem relating to locally projective spaces and its generalisation. Paul Delens : Certain problems relating to Finsler spaces. Arnaud Denjoy : Rectifiable curves. André Fouillade : The iteration of certain linear functional substitutions. Caius Jacob : Some mixed problems in a circular ring. F. Charron : An accelerometer with a rolling contact. Edouard Callandreau : The elastic state of a welded assemblage. Antoine Magnan and Claude Magnan :

A hot wire apparatus for the study of the air movements produced by the flapping wing of a bird or insect. The number of beats per second varied from 17 for the Japanese nightingale to 128 for the humblebee. The records appear to prove that the current of air is continuous and not interrupted at the end of [illegible] beat of the wings, at least in insects. J. Dufay and Ssu-Pin Liau: The absorption of light in interstellar space. From the study of various spectral types of stars, it is shown that there is no statistical relation between the colour indices and the absolute spectroscopic magnitudes, but that there exists an appreciable correlation between colour index and distance. Louis Filliâtre and Pierre Vernotte: The defects of elasticity of metals. The damping of torsion oscillations. Jean Guastalla: Researches on an equation of state for monomolecular films. Emile Sévin: Synthesis of the works of Newton, Fresnel and Maxwell. R. Bossuet: The examination of minerals for the alkali metals. An application of the spectroscopic method described in a previous communication. The rare alkaline metals are found in potash felspars and micas. Contrary to the views of Barbier, but in agreement with the results of W. Vernadsky, rubidium and lithium are found in orthoses and microclines. Thus the method for classifying the potash felspars given by Barbier fails. Marcel Schwob: The dispersion of electrical double refraction of ethyl ether. G. Liandrat: The internal photoelectric effect in liquid dielectrics. René Audubert: The electrochemical properties of electrodes photosensitised with copper salts. René Arditti: Study of the system sulphuric acid, magnesium sulphate, water. W. Graff: Thermal analysis of the system chlorine, boron trichloride. The thermal analysis gave no indication of a new chloride and consequently of no valency of boron higher than three. René Dubrisay and Mlle. Paulette Drouot: Some phenomena of surface chemistry. Desmaroux: The stability of the nitrocelluloses: the distinction between the decomposition due to internal combustion and the decomposition due to saponification. Albert Portevin and Paul Bastien: Contribution to the study of the casting of ternary alloys. F. François: The precipitation of antimony iodide and its hydrolysis. In the presence of sufficient sulphuric acid, potassium iodide precipitates a red iodide of antimony, SbI_3. This is readily hydrolysed to oxyiodide. Pierre Dubois: The action of hydrogen peroxide on permanganate. The substances obtained by this reaction have no fixed composition, varying between $MnO_{1.88}$ and $MnO_{1.93}$. Adrien Karl: The preparation of the metallic tungstates. Tungstic anhydride dissolves readily in fused common salt giving sodium tungstate (readily soluble in water) and chlorine. G. Gire: The thermal decomposition of the magnesium silicides. The magnesium silicide obtained by synthesis at 450° C. is not stable above 500° C.: at 550° C. it decomposes into magnesium and the silicide Mg_3Si_2. M. Tiffeneau, Mlle. Jeanne Lévy and F. Kayser: The unsymmetrical influence exerted by an asymmetric carbon in the action of an organomagnesium compound on an aldehyde function. The preparation of a single diastereoisomer. R. Paul: A molecular transposition accompanying the dehydration of tetrahydrofurfuryl alcohol. Raymond Quelet: The synthesis of the chlormethyl derivatives of *p*-bromanisol and of the nitroanisols. J. Colonge: The generalisation of the method of condensation of ketones by mixed aminomagnesium compounds. Paul Fleury and Raoul Paris: The comparative action of periodic acid on the α- and β-glycerophosphoric acids. P. Carré and D. Libermann: The chlorides of alkylsulphurous acids. M. Chatelet: A pyridine-iodine molecular association. Pyridine forms an unstable molecular compound with iodine with the composition $I_2(C_5H_5N)_2$. Mlle. Madeleine Roy: The alteration in castor oil by heating. The oxygen of the air is the chief cause of alteration of the oil. C. L. Sagui and A. Jourdan: Some data on the genesis of colloidal pyrrhotite and of other minerals in the mine of Bottino. R. Bureau: The rapid variation of atmospherics at sunrise. Jean Chevrier: Magnetic measurements in Syria. L. Eblé: The variation of the horizontal component of the earth's magnetic field round about days of magnetic calm. L. Tuwim: A new method for the direct determination of the natural angular distribution of the cosmic rays. C. T. Popesco: A perennial bean obtained by grafting. Mlle. M. L. Verrier: The static refraction of the eye in the cephalopods. Henri Beauvalet: The experimental study of digestion in selachians. Fontaine and Mme. Boucher-Firly: The alkaline reserve of the blood in fishes. Maurice Rangier: A form of elimination of uric acid. Gaston Menier: The apparatus studied and used at Noisiel since 1875 for lowering the temperature of the air and at the same time freeing it from dust.

Rome

Royal National Academy of the Lincei, Jan 22. F. Enriques: Continuous series composed of rational involutions of groups of points on an algebraic surface. A. Myller: Geodetic conics. F. Tricomi: Determination of the asymptotic value of a certain integral. P. Dienes: The displacement of an n-tuple, and a new interpretation of Ricci's rotation coefficients. G. Krall: Variable parameters and asymptotic provisions in some problems of celestial mechanics. G. Lampariello: The analytical nature of the solutions of canonical systems integrable by quadrature. G. Vranceanu: The geometrical interpretation of mechanical systems. C. Alessandri: The apparent velocity of the surface propagation of earthquakes in relation to the hypocentral depth. The determination of the depth of the hypocentre from time data or, more specifically, from the differences between the times of arrival at different places of a given phase of the longitudinal seismic waves, is considered. An expression is derived which indicates that, in general, the superficial velocity of propagation will appear greater when the depth of the hypocentre is great. Various numerical applications of this result are given. G. Ponte: Volcanic fumaroles. Evidence is cited which renders improbable the general opinion that volcanic eruptions are produced by the elastic force of the gases contained in the magma. So far as it has been carried to the present time, study of the phenomena bearing on fumarolic exhalations indicates that, with the exception of sodium and potassium chlorides—which originate directly from the magma—these exhalations are produced by the action of atmospheric agents on the magma at various temperatures. C. Dei: The sensitivity and the approximation of measurements of the amplification coefficients of triodes. The methods considered are those of Miller, Appleton, and Lo Surdo. G. Eibenschütz: The nature of electrodynamic forces. The possibility of deducing mathematically the production of an electrodynamic force from the movement of electrons in a conductor is demonstrated. R. DE FAZI: The chemical constitution of cholesterol, and a new isomeride of cholesterol. The action of hydrochloric acid on cholesterol under various conditions yields, in addition to the known cholesterol hydrochloride melting at 158°–158·5°, two other hydrochlorides, with melting points 136°–137° and 124°–126°. These have now been converted into isomerides of cholesterol. The structural formulæ of these cholesterols are discussed. P. PRATESI: The action of alkaline hypoiodites on the pyrrolic aldehydes. In their behaviour towards alkaline hypoiodites, the 2- and 3-aldehydo-derivatives of pyrrole exhibit analogy to the ortho- and para-aldehydes of phenol and to the naphthol aldehydes. The pyrrole-3-aldehydes lose the aldehyde group as formic acid, iodine entering the molecule to form the corresponding iodo-derivatives in almost quantitative yield. Pyrrole-2-aldehydes are less stable towards hypoiodites than their 2-isomerides; pyrrole-2-aldehyde itself gives hepta-iododipyrryl. A. QUILICO and A. DI CAPUA: Aspergillin, the spore pigment of *Aspergillus niger* (2). When extracted with dilute ammonia and precipitated with acid, aspergillin forms shining black lumps showing brown reflection and is insoluble in the ordinary organic solvents, except pyridine, although it gives up 12–14 per cent of its weight to methyl or ethyl alcohol. When heated, it behaves similarly to certain oxypyrrole blacks and it always contains a small proportion (about 0·2 per cent) of iron. Elementary analysis gives the ratios C : H : O = 5 : 4 : 2. Its molecule contains a hydroxyl group and methyl, ethyl and other derivatives have been prepared. A. ROSSI: The crystalline structure of the compound $LaAl_4$. This compound crystallises in the dimetric system and cleaves readily along the pinacoid faces (001). For the unit cell the value of a_0 is probably 13·2A. and the ratio $c : a$, 0·77. On the assumption that the unit cell contains 16 molecules, the density is calculated to be 3·69, which agrees moderately well with the pyconometric value, 3·86. The symmetry class is not determinable with certainty. T. LIPPARINI: *Rzehakina epigona* (Rzehak), a foraminifer of archaic type in the Bologna Tortonian. T. CARPANESE: The mineral deposits of Monte Rosso di Verra (Monte Rosa group) (2). Owing to its marked crossed dispersion, its associations with olivine, and the orientation of the two minerals in these associations, the titanolivine of Monte Rosso is more nearly analogous to that of Val Malenco than to the titanolivines and titanohumites of other deposits. The optical properties of the amphibole present indicate that this mineral is a form intermediate to green hornblende and actinolite.

Forthcoming Events

Tuesday, June 27

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—Annual General Meeting. Capt. T. A. Joyce: Presidential Address.

Thursday, June 29

ROYAL SOCIETY, at 4.30.—Prof. R. G. Harrison (professor of comparative anatomy at Yale University): "The Origin and Development of the Nervous System studied by the Methods of Experimental Embryology" (Croonian Lecture).

ASSOCIATION OF TECHNICAL INSTITUTIONS, June 29–July 1.—Summer Meeting at the Municipal College of Technology, Manchester. Sir Hugo Hirst: President.

Official Publications Received

GREAT BRITAIN AND IRELAND

Observations made at the Royal Observatory, Greenwich, in the Year 1931, in Astronomy, Magnetism and Meteorology, under the direction of Sir Frank Dyson. Pp. viii + A62 + B7 + Cix + C74 + [illegible] + E49 + 19. (London: H.M. Stationery Office.) 30*s.* net.

Department of Scientific and Industrial Research. Summary [illegible] Progress of the Geological Survey of Great Britain and the Museum of Practical Geology for the Year 1932. Part 1. With Report of the Geological Survey Board and Report of the Director. Pp. iv + 96. (London: H.M. Stationery Office.) 2*s.* net.

Journal of the Chemical Society. May. Pp. iii + 469–557 + viii. (London: Chemical Society.)

University of Reading: The National Institute for Research in Dairying. Annual Report for the Year ending 31st July, 1932. Pp. 78. (Reading.)

Annals of the Natal Museum. Edited by Dr. Ernest Warren. Vol. 7, Part 2, May. Pp. 145–301 + plates 7–15. (London: Adlard and Son, Ltd.). 17*s.* 6*d.* net.

OTHER COUNTRIES

The Quarterly Journal of the Geological, Mining and Metallurgical Society of India. Edited by K. K. Sen Gupta. Vol. 4, No. 4, December 1932. Pp. 119–174 + plates 9–12. (Calcutta.) 6 rupees.

Commonwealth of Australia: Council for Scientific and Industrial Research. Bulletin No. 72: Varieties of Wheat in Australia; a Catalogue, with Pedigree or Source, and a Genealogical Chart showing the Relationships of the More Important Varieties. By J. R. A. McMillan. Pp. 28. Bulletin No. 73: A Soil Survey of the Nyah, Tresco, Tresco West, Kangaroo Lake (Vic.), and Goodnight (N.S.W.) Settlements. By J. K. Taylor, F. Penman, T. J. Marshall and G. W. Leeper. Pp. 47 + 4 maps. (Melbourne: H. J. Green.)

Proceedings of the Academy of Natural Sciences of Philadelphia. Vol. 84, 1932. Pp. iii + 536 + 33 plates. (Philadelphia.) 6.25 dollars.
